A KEY TO THE HARMSWORTH SELF-EDUCATOR

From this table of the 25 groups of the Self-Educator the student may find the place of any subject treated in the work. The main groups appear in regular numerical order in each part of the Educator, each group continuing until complete. The sub-divisions of the groups appear as nearly as possible in the order of this page.

Group 1. Success

The Secrets of a Successful Life. Personality. Applied Education. Ideas. The Qualities that Win in the World.

Group 2. Geography and Travel

GEOGRAPHY. Physical, Political, and Commercial.
TRAVEL. Educational Travel. How to See the World.

Group 3. Arts and Crafts

ART. Ideals and History of Art. The Old Masters.
DRAWING. Freehand. Object. Brush. Memory. Light & Shade.
PAINTING. Theory and Training.
DESIGN. Design in Crafts and Trades. Book-decoration. Illumination. Design for textiles, wallpapers, metal work.
SCULPTURE. Modelling. Chiselling. Casting.
ARCHITECTURE. Theory. Styles. Training.
CARVING. Wood. Bone. Ivory. Tortoiseshell.
ART METAL WORK. A Practical Course.
PHOTOGRAPHY. A Course of Simple Lessons with a Camera.

Group 4. Physiology and Health

PHYSIOLOGY. Structure and Working of the Human Body.
HEALTH. The Laws of Health and Personal Hygiene.

Group 5. Agriculture and Gardening

FARMING. A Practical Course in the Cultivation of the Earth. Live-stock. Dairying. Poultry. Beekeeping.
FORESTRY. The Theory and Practice of Managing Trees.
GARDENING. Gardens for Pleasure and Profit.

Group 6. Chemistry

CHEMISTRY. Complete Course in Theory and Practice.
APPLIED CHEMISTRY. The Applications of Chemistry in Industry. Chemical Analysis. Acids and Alkalies. Oils and Fats. Waxes. Candles. Soap. Glycerine. Volatile Oils and Perfumes. Paints and Polishes. Glues. Starch. Inks. Coal Tar Products. Wood Distillation. Celluloid. Matches. Artificial Manures. Electro-chemistry. Water-Softening. Waste Products. Artificial Silk.

Group 7. History

The Story of All Ages and Peoples for Over Ten Thousand Years—From Egypt and Babylon to Europe in 1914.

Group 8. Civil Engineering and Transit

CIVIL ENGINEERING. Surveying. Varieties of Construction. Reinforced Concrete. Roads. Bridges. Railways and Tramways. Water Supply. Sewerage. Refuse. Hydraulics. Pumps. Harbours. Docks. Lighthouses.
VEHICLES. Construction and Use. Cycles. Cabs, Buses, Trams.
MOTORS. Design and Management of a Motor Car.
AVIATION. Science and Management of Flying Machines.
RAILWAYS. The Management and Control of Railways.
SHIPBUILDING. Shipping. Design and Construction.

Group 9. Literature and Journalism

LITERATURE. A Survey of English Literature and Foreign Classics. The World's Great Books and their Writers.
JOURNALISM. How to Become a Journalist. A Guide to Newspaper Life. How to Write. The Journalist's System.
PRINTING. Composing by Hand and Machine—Linotype and Monotype. Stereotyping and Printing.
TYPE. Type Cutting and Founding.
ENGRAVING AND ETCHING. Blockmaking and Process Work.
LITHOGRAPHY. Printing from the Stone.
BOOKBINDING AND PUBLISHING. Binding and Issuing Books.

Group 10. Civil Service and Professions

CIVIL SERVICE. The Three Branches of the Public Services of the British Empire—Municipal, National, Imperial.
BANKING. The Whole Practice of Banking.
LAW. How to Become a Solicitor or Barrister.
MEDICINE. Training of a Doctor, Veterinary Surgeons. Dentists. Chemists and Druggists. Nurses.
INSURANCE. Health. Unemployment. Life. Fire. Accident.
AUCTIONEERING AND VALUING. Practical Training.
ESTATE AGENCY. Management of a Great Estate.
CHURCH. How to Enter the Ministry of all Denominations.
SCHOLASTIC. Teachers. Professors. Governesses. Tutors.
SECRETARIES. Institution Officials. Political Agents. Lecturers.
LIBRARIES. Management of Libraries. Cataloguing.
ARMY, NAVY, MERCHANT SERVICE. How to Enter Them.

Group 11. Life and Mind

BIOLOGY. The Rise of Life. Evolution. Heredity.
PSYCHOLOGY. The Mind of Man.
SOCIOLOGY. Social Conditions. Welfare of Communities.
EUGENICS. Human Betterment and the Future of the Race.

Group 12. Business

BUSINESS. The Management of a Successful Business. System. Simple Political Economy.
SHOPKEEPING. All Kinds of Shops and Small Trades.
ADVERTISING. The Value of Advertising. How to Advertise, How to Write Advertisements. How to Get Them.

Group 13. Physics and Power

PHYSICS. The Science of Matter and Motion.
POWER. Sources and Uses of Power. Air. Water. Wind. Sun. Steam. Oil. Gas. For Electricity, see Group 16.
PRIME MOVERS. Structure and Management of all Engines.

Group 14. Building Trades

BUILDING. The Building Trades and Building Materials: their Manufacture and Use. Building a House. Excavating. Drainage. Bricks, Limes, and Cements. Bricklaying. Clay Wares. Reinforced Concrete. Masonry. Carpentry. Slates and Tiles. Plumbing. Joinery. Foundry and Smith's Work. Painting. Papering and Glazing. Heating. Lighting. Ventilation. Quantity Surveying.
WOOD-WORKING MACHINERY. The Machines Used in Working Wood: Sawing, Turning, Planing, Moulding.
CABINET-MAKING AND UPHOLSTERING.

Group 15. Natural History

BOTANY. Flowers. Plants. Seeds. Trees. Ferns. Mosses. Fungi.
ZOOLOGY. Mammals. Birds. Fishes. Reptiles. Insects. Lower Forms of Life.
BACTERIOLOGY. The Story of Microbes. Bacteriology in Relation to Health and Industry.

Group 16. Electricity

ELECTRICITY. Its Development and Countless Applications. Electrical Engineering.
TELEGRAPHS AND TELEPHONES. The Instruments and How to Operate Them.
WIRELESS TRANSMISSION. The Main Systems and their Methods of Working.

Group 17. Music

OLD NOTATION AND TONIC SOLFA. Tuition in All Instruments. Orchestration.
ELOCUTION AND SINGING. The Voice and its Treatment.
MUSICAL INSTRUMENTS. Their Design and Manufacture.

Group 18. Manufactures

TEXTILES. The Textile Trades from Beginning to End. Cotton. Wool. Silk. Hemp. Flax. Jute. Carpets.
LEATHER. The Leather Industry. Tanning. Boots and Shoes. Saddlery. Belting. Gloves. Sundry Leather Goods.
GLASS. Manufacture of All Kinds of Glass. Stained Glass.
EARTHENWARE. The Craft and Industry of Pottery.
PAPER. Papermaking of All Kinds.
RUBBER. The Source and Preparation of Rubber, and Manufacture of Rubber Goods.
TOBACCO. Cultivation and Manufacture. Tobacco Pipes.
FOOD SUPPLY. Milling. Breadmaking. Biscuits and Confectionery. Sugar. Condiments. Fruit. Fisheries. Food Preservation.
BEVERAGES. Tea. Coffee. Chocolate. Cocoa. Brewing. Wines and Ciders. Mineral Waters.
BASKETMAKING. CORK. WATTLE. CANE. BARKS. BRUSHES.

Group 19. Astronomy. Geology. Archæology

ASTRONOMY. The Universe as We Know It. Millions of Worlds. A Survey of the Solar System.
GEOLOGY. The Structure of the Earth. Petrology. Crystallography. Palæontology.
ARCHÆOLOGY. Buried History. The New Story of the Old World as Revealed by the Excavator.

Group 20. Mechanical Engineering

ENGINEERING. Applied Mechanics. Workshop Practice. Machine Tools. Machines and Appliances. Cranes.
DRAWING for Coppersmiths, Tinmen, and Boilermakers.

Group 21. Languages

LATIN. ENGLISH. FRENCH. GERMAN. SPANISH.

Group 22. Dress and Housekeeping

DRESS. Principles of Dressmaking. Underclothing, Tailoring. Millinery. Hatters. Furs and Feathers
HOUSEKEEPING. Domestic Management. Servants and their Duties. Cookery. Laundry.

Group 23. Metals and Minerals

METALS. Metallurgy. Properties and Characteristics of Metals. Iron and Steel. Copper. Tin. Zinc. Precious Metals.
METAL MANUFACTURES. Arms and Ammunition. Cutlery. Clocks and Watches. Jewellery. Scientific Instruments.
MINERALS. Mineralogy. Properties and Characteristics of Minerals.
MINING. Coal. Gold. Diamonds. Tin.
QUARRYING. The Appliances and Processes of Extracting and Preparing Stone.
GAS. The Process of Manufacture.
PETROLEUM. Extraction and Refining Processes.

Group 24. Clerkship

ACCOUNTANCY. Complete Training. Bookkeeping.
SHORTHAND. Pitman's System, with Latest Improvements
TYPEWRITING. Working and Management of All Machines

Group 25. Mathematics

Arithmetic. Algebra. Simple Graphs. Euclid. Trigonometry.

Coalfields and their Resources. Petroleum and its Uses. Iron and Steel. Gold and Silver. Other Metals. Precious Stones.

THE WORLD'S MINERALS

Coal is derived from the vegetation of past geological epochs, subjected for vast periods of time to great pressure and heat. The result of a long series of slow chemical changes is to get rid of a large proportion of the hydrogen and oxygen, and to increase the proportion of carbon [see Natural History]. *Peat*, abundant in the bogs of Ireland and other parts of the world, shows an early stage of the process. The fibrous arrangement is still clearly seen. There is a large proportion of water, and owing to the smaller proportion of carbon the heating power of compressed peat is only about one quarter of that of coal. *Lignite*, with 70 per cent. or less of carbon, is intermediate between peat and coal, but the harder varieties, known as brown coal, closely resemble the latter. Some of the vast lignite deposits of North America are an excellent substitute for coal.

The Two Kinds of Coal. Of coal there are two well-marked kinds—soft or bituminous coal, with 50 per cent. or more of carbon, and anthracite, with as much as 94 per cent. *Bituminous coal* lights readily, burns with a flame, and produces a varying amount of smoke. Its varieties are very numerous, one of the best marked being the well-known cannel coal. *Steam coal*, intermediate between bituminous coal and anthracite, contains little bitumen, so that it is smokeless, while the high proportion of carbon gives great heating power. This steam coal is in great demand for naval use. *Anthracite* is hard to light, burns without flame, and gives out great heat. Its smokelessness makes it very suitable for use in cities, as in the United States. It is also used in brewing.

Coke is produced by heating bituminous coal away from the air. The volatile substances are driven off, and the residuum approximates in properties to anthracite. Coke is an important by-product in the manufacture of coal gas. It burns with intense heat, and its freedom from sulphur makes it valuable in many metallurgical operations. Coals are often spoken of as coking, or non-coking. The former, which cake or fuse in burning, are preferred for special purposes—for example, as fuel for locomotives.

Growth of the Use of Coal. The use of coal is of no great antiquity in Europe. Whatever may have been the case locally, it was not used in London before the thirteenth century. In the seventeenth century the total production in England had reached over 2,000,000 tons. The introduction of steam power enormously increased the consumption of coal, and resulted in a redistribution of population in England and other countries.

Coalfields of the World. Estimates of the total area of the world's coalfields differ widely. The area can hardly be far under 500,000 sq. miles. According to Mr. Chisholm, there are approximately 250,000 sq. miles in North America, chiefly in the United States. The coalfields of China cannot be less than 200,000 sq. miles, and may be more. The coalfields of Britain may be put at about 12,000 sq. miles, while those of the Empire are roughly 140,000 sq. miles. Russia has about 20,000 sq. miles; Spain, 5,000; France, Germany and Austria-Hungary, round about 2,000; and Belgium, 500 sq. miles. Area, however, affords no satisfactory basis for estimating the actual resources. Much coal lies at a depth impossible to work, as, for example, on the South Wales coalfield, where the coal-bearing strata are 10,000 ft. thick. In other cases the seams may be so thin as not to pay for working, or the quality may be inferior. Temperature increases rapidly though not uniformly with the depth of a mine, rendering extraction beyond a certain depth a physical impossibility [see Mining]. The element of cost has also to be taken into account in deep mining. At the present time a depth of 4,000 ft., and a seam thickness of 2 ft. are commonly assumed as working conditions. No mine yet reaches this depth, though the deepest mines of this country and of Belgium are not far short of it.

How Long Will Our Coal Supply Last? The ever increasing demand for coal has led to investigations into the probable duration of our coal supply. Two Royal Commissions have reported on the subject, the second in 1904. On the workings of 1903 our reserves would apparently last for 600 years, but the output is not likely to remain steady. More probably it will reach a maximum within no distant period, and then almost imperceptibly decline owing to the gradual increase of working cost.

The largest coalfields of Britain are those of (1) Central Scotland, in the rift valley between the Scottish Highlands and the Southern Uplands; (2) South Wales; and (3) the marginal coalfields of the Pennines in the north-east, south-east, and south-west.

The Coalfields of Scotland. The Scottish coalfield is divided into the Ayrshire coalfield, the Central, or Forth and Clyde coalfield; the Fife coalfield; and the Midlothian coalfield. The estimate furnished to the Royal Commission of 1904, was that more than 15,000,000,000,000 tons are available, including workable coal under the Firth of Forth. The bulk of this is in the counties of Fife (with Kinross), Lanark, the

Lothians, Stirling, and Ayrshire. The output for 1913 was 42,500,000 tons, two-fifths of which came from Lanarkshire, which feeds the great industrial region of which the Clyde is the centre and outlet.

The South Wales Coalfield. The South Wales coalfield ranks next in size, with an area of over 900 sq. miles. Deeply cut valleys penetrate into this mountainous region, bringing the outcrop to the surface and enabling the seams to be worked cheaply. This explains why the mines are long and shallow as compared with those of the North of England, though many are now carried to over 10,000 ft. The ports at the mouths of the valleys, of which the most important are Llanelly, Swansea, Cardiff, Barry, and Newport, are well placed for exporting coal cheaply. Much is used locally for iron smelting, the tinplate and other manufactures. The eastern part of this field consists of bituminous coal. The centre supplies most of the steam coal for the Navy, while anthracite is mined in the western part. More than 26,000,000,000 tons are estimated to be available within 4000 ft,, half being steam coal. At the rate of output in 1903 (42,000,000 tons) this would last about 600 years. In 1913 the production amounted to nearly 57,000,000 tons, forming 19.8 per cent. of the total output from the United Kingdom.

The Coalfields of the North of England. The coalfield of Yorkshire, Derby, and Nottingham, the largest in England, is about 750 sq. miles in area. The Silkstone is one of the best seams. It is continuous with the Arley coal of the Lancashire coalfield, and must originally have covered an area of 10,000 sq. miles. The Barnsley coal is of a semi-anthracite character, developing a great heat either as engine or smelting fuel. The estimated amount of workable coal in 1903 was over 26,000,000,000 tons, available for 500 years at the rate of 1903 (52,000,000 tons). This coalfield supplies the Yorkshire woollen and iron industries. In 1913 the output was 74,000,000 tons, or 25·8 per cent. of the total for the whole country.

The Durham and Northumberland coalfield also lies east of the Pennines. The seams which run under the sea might probably be followed for about three miles. A famous seam is the Wallsend, five or six feet thick. Newcastle coal is in great demand in London, and also locally for the vast iron industries of the Tyne and Tees. The output in 1913 was over 56,000,000 tons. The area of visible coalfields was estimated at 460 sq. miles, in addition to 225 sq. miles of concealed coalfields and 111 sq. miles under the sea. The amount of workable coal was estimated in 1903 at nearly 9,000,000,000 tons.

Two important coalfields, those of Cumberland and Lancashire, lie on the western flank of the Pennines. In the Cumberland coalfield all the coal lies within 2000 ft. of the surface. It is chiefly mined round Whitehaven, Workington, and Maryport, and the workings have been carried about three miles under the Irish Sea. The amount of coal available has been estimated at 1,500,000,000 tons, which at the rate of 1903 (over 2,000,000 tons) would last about 700 years.

The South Lancashire coalfield, which extends into Cheshire, is an irregular area of over 200 sq. miles. Its output in 1913 was not far short of 25,000,000 tons, a large part of which feeds the great cotton and iron industries of Lancashire. The southern part of this coalfield is one of the most densely populated parts of Europe. The estimated reserve is 4,340,000,000 tons.

Coal for the Black Country. The North Staffordshire coalfield is not very large (75 sq. miles), but it has thick seams of workable coal. The coal-bearing strata are perhaps 5000 ft. thick, with a total thickness of workable seams amounting to nearly 3000 ft. Workings are carried down to nearly 3000 ft. This region is not yet developed to anything like the extent possible, since few districts in the United Kingdom are so richly endowed with mineral wealth. The South Staffordshire coalfield, on the contrary, once enormously rich, has been much depleted to feed the furnaces of the Black Country. The whole country between Wolverhampton, Dudley, and Birmingham forms one great workshop [see **68**, page 820]. Professor Hull has vividly described the scene at night, as viewed from the walls of Dudley Castle, in the centre of the coalfield: "The whole country within a radius of five or six miles is seen to be overspread by collieries, iron-foundries, blast-furnaces, factories, and the dwellings of a dense population, and from amidst the thick, smoky atmosphere the tongues of fire from the furnaces shoot up an intermittent light which illumines the whole heavens. But the spectacle does not represent the whole sum of human labour, for whilst 10,000 hands are at work above ground, one half as many, perhaps, are beneath the surface, hewing the coal which is to be the prime mover of the whole machinery in motion above ground." The total thickness of the workable seams in the Dudley district is about 65 ft., a famous seam being the Ten-yard, with a general thickness of 30 ft. Probably nine-tenths of this rich seam are now worked out, drowned, or otherwise destroyed. In this area of 93 sq. miles there are perhaps 1,350,000,000 tons still available. In 1913 over 14,000,000 tons were raised in the two Staffordshire coalfields.

The Warwickshire coalfield has the advantage of being the nearest to London. The area at present worked is about 30 sq. miles, with perhaps 30 ft. of workable seams. It may yield nearly 850,000,000 tons. The output in 1913 was just over 5,000,000 tons.

Some Minor Coalfields. The Bristol coalfield, which extends to Gloucester and over much of Somerset, has two series of coal-bearing strata, separated by harsh sandstones. The total area has been put down at 150 sq. miles, of which all but 45 sq. miles are concealed by more recent formations. The output in 1913 was about 1,250,000 tons, and it is estimated that over 4,000,000,000 tons might be available. Of this more than one-eighth is steam coal, suitable for the Navy.

There are numerous smaller coalfields, such as those of North Wales, Coalbrookdale, the Forest of Dean, and the recently discovered deposits in Kent from which nearly 60,000 tons were obtained in 1913. The total output for the whole of England in 1913 was practically 200,000,000 tons, while Wales produced about 45,000,000 more. The total for England and Wales was thus nearly 245,000,000 tons, giving a total for Great Britain of over 287,000,000 tons, the value at the pit's mouth being £145,000,000.

The Irish coalfields are small and little developed. The most important are those of Dungannon in Ulster, and of Kilkenny in Leinster. The output in 1913 was only 82,000 tons. About 175,000,000 tons are estimated to exist.

Total Coal Resources of Britain. The recent Royal Commission estimated that there

existed reserves of coal amounting to nearly 101,750,000,000 tons in visible coalfields and to over 39,000,000,000 tons in concealed coalfields. This vast amount, enough at the rate of 230,000,000 tons a year to last for six centuries, includes none more than 4000 ft. below the surface, or more than three miles under the sea. The value of the estimated output is about £95,000,000 annually.

The quantity of British coal exported has for several years exceeded 65,000,000 tons. In 1913 it was over 76,000,000. This does not include bunkerage for consumption on board ship, which amounted in 1913 to over 21,000,000 tons, making a total of nearly 97,000,000 tons, or over 30 per cent. of the output. France, Germany, and Italy are the largest importers.

For a list and map of the British coalfields, see pages 820, 821, and 1070; and for coal as an index of the producing power of nations, see page 866.

Russian Coalfields. The coalfields of Russia are nearly twice as great in area as those of Britain; those of Spain are less than half as great as our own. Here, again, area is not the proper basis of calculation, for Germany, with less than one-tenth of the actual area of the Russian coalfields, is the third largest producer in the world.

The coalfields of Russia are found (1) in Southwest Poland; (2) in the Donets basin, covering an area of over 10,000 sq. miles, the most important coalfield, with an annual output of over 20,000,000 tons; (3) in Central Russia round Moscow; and (4) in the Urals. Beyond the confines of European Russia are the coalfields of the Caucasus and the Altai. The Moscow, Donets, and Polish coalfields are all developing rapidly. The present output of Russia is about 30,000,000 tons, valued at nearly £15,000,000.

Spanish, French, and Belgian Coalfields. Between Santander and Oviedo is the potentially rich coalfield of Asturias, with 60 workable seams of good quality. There are also rich deposits in Eastern Spain. The present output, however, is small, being about 3,000,000 tons, valued at less than £2,000,000.

The important Franco-Belgian coalfield stretches from near Aachen to Calais (210 miles), where the strata dip beneath the Channel, to reappear near Dover and in the Bristol coalfield. On this coalfield are the iron towns of Liége, Namur, and Mons in Belgium, the cotton town of Lille in France, and many smaller industrial towns in both countries. The total area is about 1200 sq. miles, but the strata are in places interrupted by or buried beneath the chalk.

In Central France, on the flanks of the Central Plateau, are many small fields, of which St. Etienne is the busiest centre. This also supplies the silk industry of Lyons.

The present output of France exceeds 40,000,000 tons, valued at £25,000,000. The Belgian output is 22,000,000 tons, valued at £15,000,000.

The Coalfields of Central Europe. The Saar coalfield (900 sq. miles), occupying the valley of the Saar, a right-bank tributary of the Moselle, supplies the rapidly growing industries of Alsace-Lorraine. The strata probably descend to 20,000 ft., so that the full resources can never be utilised.

The Westphalian or Ruhr valley coalfield is the most important in Germany, extending from the Rhine at Duisburg and Ruhrort for about forty miles up the Ruhr valley. The great iron towns of Essen and Barmen-Elberfeld are on the coalfield, which also exports coal by the Rhine.

The other important coalfields are in Saxony, on the flank of the Erz Gebirge, or Ore Mountains, and in Silesia, on the flanks of the Riesen Gebirge, and in the extreme south-east at the western end by the Polish field. The total output of Germany is about 175,000,000 tons, valued at £92,000,000. In addition there is an annual production of 80,000,000 tons of brown coal, or lignite, valued at about £9,000,000.

In Austria-Hungary coal is found in Bohemia, Moravia, and Silesia, in the flanks of the Central European Highlands. There is practically no coal in the Alpine provinces, but some lignite is found in Styria. The output of coal is 16,000,000 tons, of the value of nearly £7,000,000; 26,000,000 tons of brown coal are also produced, valued at about £6,000,000.

In the other countries of Europe, coal production is unimportant.

The Coalfields of Asia. China probably possesses the largest and richest coalfields in the world. The province of Shansi, in Northern China, has seams of coal 40 ft. thick, and easily accessible. Iron is also abundant, and the whole region is destined to become a second and richer Pennsylvania. The deposits are continued in the adjoining province of Honan. In the Yangtse basin of Central China, and especially in the Red Basin of Szechwan, coal is exposed in the gorges of the Yangtse and its affluents, needing only to be followed by adits, as in South Wales. There are also coalfields in Hunan and Kwangtung in Southern China, in Manchuria, and in Korea. The present output in China is estimated at 13,000,000 tons, of which nearly half is anthracite. Japan has coalfields in Kiushiu, Yezo, and Formosa. The Japanese output of 19,000,000 tons is valued at over £6,000,000. In Tongking there are coal-seams 70 ft. thick. Still farther south, coal is found in Borneo.

Coal is found in many parts of India, but most abundantly in Northern India. The most important coalfield at present worked is that of Raniganj (500 sq. miles), which is situated about 120 miles from Calcutta. The output of India is at present over 14,000,000 tons.

Australasian and African Coalfields. Important coalfields lie between the Great Dividing Range and the Pacific Ocean, in New South Wales and Queensland. Newcastle, at the mouth of the Hunter River, is the outlet for the mines of that district. At Brisbane, the capital of Queensland, says Professor Hull, quoting the famous Australian geologist Clarke, "steamers can load by lying literally at the mouth of the mines," for the coal-seams are exposed close to the sea, and are accessible by adits. Tasmania is also well provided with coal. In New Zealand, North Island has considerable deposits of lignite, while South Island has both lignite and coal.

Africa is poorly provided with coal in comparison with the other continents. A little is found in Abyssinia and British East Africa, but the rich coalfields of the continent are south of the Zambezi, in British territory. Large deposits of good coal occur in Rhodesia, the Transvaal, and the Orange River Colony. Good bunker coal is obtained from Newcastle and Dundee in Natal, and there are also deposits in Eastern Cape Colony. If, as some geologists think, these are parts of a single great coalfield, the potential resources of South Africa are considerable.

Coalfields in the New World. Coal is very unequally distributed in the New World. In South America it occurs in parts of Venezuela, Southern Brazil, Uruguay, Argentina—including Southern Patagonia and Tierra del Fuego—Chile, and Peru, but not to any great extent. The output of Chile, though increasing, is not yet large.

The coalfields of North America vie with those of Eastern Asia in extent and value.

Rich coalfields are worked in Nova Scotia in the east and in Vancouver Island in the west of Canada, the Nanaimo mines of the latter yielding the only good coal of the Western Pacific shores. In the interior, coal occurs from Manitoba westwards, especially in the Rocky Mountains, but owing to the lack of communications and population only a fraction is worked. The coalfield west of the Crow's Nest Pass, now reached by the railway, is said to be one of the most extensive deposits in the world. Large deposits of lignite are found in Alberta. Unfortunately, Eastern Canada, the most densely populated part, is destitute of coal, and imports much from the United States, Buffalo being the chief lake port.

Coal in the United States. The United States ranks first among the coal-producing countries of the world, with an output in 1912 of 477,000,000 tons, valued at nearly £145,000,000. Coal is said to underlie about one-sixth of the country, but estimates of the total area of the coalfields vary considerably. Those of the late Professor Rogers made it about 197,000 sq. miles, but the later estimates of Professor Hitchcock raise it to nearly 230,000 sq. miles. Other estimates put it at a still higher figure. The figures given below are those of Professor Hitchcock. Bituminous coal is mined in twenty-five States, Pennsylvania, Illinois, Western Virginia, and Ohio coming first. Much coal is locally used, especially in the busy region round the Upper Ohio.

The coalfields of the United States are (1) the Appalachian field, extending from New York to Alabama, a distance of 900 miles, through the States of Pennsylvania, Maryland, West Virginia, Ohio, East Kentucky, Tennessee, Georgia, and Alabama. In West Virginia the thickness of coal is about 50 ft. The total area of the coalfield is over 63,000 sq. miles. The coal is often exposed in the deeply cut mountain valleys, so that it can be easily and cheaply worked. The numerous rivers transport it cheaply to the towns and industrial centres. Its combination with iron in Western Pennsylvania has created the great iron industries which centre round Pittsburg. In this region, and especially at Connellsville, is made three-quarters of the coke of the United States, used chiefly in the pig-iron industry. The output of Pennsylvania is about 143,000,000 tons of bituminous coal. New York ranks next to London as a coal market.

The Central Coal Basin, east of the Mississippi, in the States of Illinois, Indiana, and Western Kentucky, is over 51,000 sq. miles in extent, with a maximum of 30 ft. of coal. The northern or Michigan basin is small, under 7000 sq. miles, with a maximum of 11 ft. of coal. West of the Mississippi is the vast West Central or Missouri coalfield, with an area of over 100,000 sq. miles, in the States extending from Iowa to Texas, and including parts of Nebraska, Missouri, Arkansas, and Indian Territory. Much of the Texas coal, however, is poor in quality. There is also coal in parts of the Rocky Mountains and in parts of the Pacific coast.

A Vast Deposit of Anthracite. Pennsylvania also leads in the production of anthracite, turning out about 75,000,000 tons a year. The deposit area of anthracite, Susquehanna, Lehigh, and the Schuylkill valleys of Eastern Pennsylvania, is estimated at about 450 sq. miles. A species of anthracite, resembling graphite and very difficult of combustion, is found in the New England basin, estimated at 750 sq. miles in area. Small deposits are also found in Colorado and New Mexico. Lignite is abundant in the western part of the Central Plain and round the Gulf of Mexico.

Most of the United States coal is absorbed by the home market, though increasing quantities are exported to Canada, the West Indies, Central and South America.

In Mexico coal is found in several parts, but at a height of from 2000 to 4000 ft. above the sea. There is also some coal in Central America and the West Indies.

The world's output of coal thus now amounts to over 1,229,000,000 tons a year, of which the British Empire supplies about one-fourth.

Petroleum. Petroleum is a liquid mineral product, stored in subterranean reservoirs. These are generally reached by boring, but there are also "gushers," or free-flowing wells, yielding many thousands of gallons daily, much of which runs to waste before storage apparatus can be erected. The crude oil is usually carried in pipes to the centres from which it is distributed, refined or unrefined, as the case may be, by pumping it into tank cars or tank steamers.

Petroleum is widely distributed. It is found in Germany, Galicia, Rumania, and on a vast scale in Southern Russia, in Transcaucasia. Valuable deposits are found in Persia, and now furnish supplies to the British Navy. The petroleum of the oilfields of Burma is carried by pipes to Rangoon, for the Indian market. The line of deposits is continued in the islands of the Eastern Archipelago (Java, Sumatra, Borneo, the Philippines), near Sydney, in New South Wales, and in New Zealand. Africa has workable deposits in Algeria and Cape Colony. The oilfields of North America vie with those of Russia. Those of South America (Peru, Venezuela, Argentina) are less considerable.

Baku, on the Caspian Sea, is the chief centre of the Russian oil industry, which in 1912 produced nearly 2856 million gallons, forming one-fifth of the world's total production. Much of the output goes across the Caspian to Astrakhan and the Volga for the European markets. Some is distributed through Batum and Poti, on the Black Sea. The restriction on sending oil in bulk through the Suez Canal is now removed, and Port Said is the depot for the Eastern market.

Petroleum in the New World. The United States furnishes over three-fifths of the world's total supplies; in 1912 the production amounted to over 9000 million gallons, valued at £32,000,000. The first boring for petroleum in the United States was made in Pennsylvania in 1859. The product was refined round Pittsburg and Oil City. This region is still very productive, with 20,000 wells and several thousand miles of pipes leading to the refining and exporting centres on the Great Lakes and the Atlantic coast. California alone produces two-fifths of the total output, and along with Oklahoma and Illinois supplies 75 per cent. The production of Oklahoma has increased from 50,000 gallons in 1901 to over 2000 million gallons in 1912.

THE GREAT ABYSS IN WHICH DIAMONDS LIE

ONE OF THE MOST PRECIOUS MINERAL SOURCES OF THE WORLD—A GREAT DIAMOND MINE AT KIMBERLEY

The distillation of petroleum is said to yield 200 different products which are widely used in the industrial arts. The lighter oils, known in the United States as kerosene, are used for lighting, the heavier (American paraffin) for heating and lubricating machinery. Oil fuel for steamers and trains, already used to some extent, has probably a great future. Other products, all highly inflammable, are naphtha, gasolene or petrol, benzene, benzoline, and rhigoline, the latter used to cause local anæsthesia by rapid evaporation. The residuum yields paraffin and vaseline. The former is used in making candles and to insulate electric wires. Ozokerit, a very similar substance of natural origin, found in Galacia and Utah, is put to the same uses British paraffin oil and paraffin wax are distilled from bituminous shale near Edinburgh. Similar shales are worked in New South Wales and Queensland.

Natural gas occurs in many parts of the United States, but is commercially important only in West Virginia, Pennsylvania, Oklahoma, and Ohio, where it is carried by pipes to the industrial centres. It has special advantages in glassmaking, which has become important in Western Pennsylvania.

Asphalt, used in street paving, can be obtained from petroleum, but its commercial sources are the natural deposits in Barbados, Trinidad, Venezuela, Algeria, the Swiss Jura (Val de Travers), and other parts of Europe.

Iron and Steel. Iron ranks next to coal in commercial importance. Directly or indirectly, it is used in nearly all industrial undertakings, so that the material condition of a country can be roughly estimated by the annual consumption of iron. In the United Kingdom and the United States it amounts to about 300 lb. per head of the population, against less than 3 lb. in India. Iron is said to occur pure in Greenland, but elsewhere it is mixed with carbon, sulphur, phosphorus, and other impurities. [See METALS AND MINERALS.] The principal iron ores are (1) the black oxide or magnetic iron of Sweden, the Urals, Canada, and the United States; (2) the red or brown hæmatites of Northern Spain, Elba, France, Germany, and the British Isles. In England there are deposits 15, 30, or 60 ft. thick in the Furness district. The purer carbonates of iron are known as spathic ore, the less pure as clay ironstone and blackband ores. The Eisenerz district of Styria is the chief source of spathic ore. Some spathic ores are rich in manganese, which plays an important part in the Bessemer process. [See below.] The clay and blackband ores are very common in Britain. The sulphides, or iron pyrites, are valuable only for the sulphur they contain, a minute percentage of sulphur being extremely injurious in iron.

The Supply of Iron. Iron is very widely distributed over the world, but the United States, the United Kingdom, and Spain are the chief sources. The best ores are those of Canada, Lake Superior, Sweden, and Algeria. The chief ironfields of Britain are in the Scottish coalfield; on the Cumberland coalfield, including the Furness district of Lancashire; round the Tyne and Tees, including the Cleveland district of North Yorkshire; on the Yorkshire coalfield, especially round Sheffield; in many parts of the Central Plain, especially on the coalfields, and on the South Wales and Bristol coalfields. [See map, page 820.]

In the United States the Northern Appalachian region (Pennsylvania and New York) has in recent years been passed by the Lake Superior region (Minnesota, Michigan), which produces four-fifths of the total, and by the Southern Appalachian (Birmingham, Ala.).

Iron occurs either at the surface or at considerable depths. The Bell Island mines of Newfoundland are really an open quarry of red hæmatite. Some of the famous iron ores of Lake Superior can be extracted by steam-shovels, the daily output of each shovel being from 1500 to 2000 tons.

Iron enters into commerce as pig iron, cast iron, wrought iron, and steel.

Iron Smelting. To remove impurities, iron must be smelted. Before the use of coal, the fuel was charcoal, but only very pure ores could be used. The iron industry was then confined to forested dstricts such as the Forest of Dean, in this country, or the Weald, which was gradually deforested by the ironworkers. The black oxide occurs in rocks in which coal is very seldom found, and these ores are still smelted with charcoal in Sweden and Russia—both forest countries. The process is much dearer, but a much better result is obtained. With the introduction of coal fuel the iron manufacture shifted to the coalfields. In our own country, coal and iron generally occur together. This is one of our great commercial advantages. Where they do not occur together it is more economical to carry the ore to the fuel, for the equivalent of two tons of coal is needed to turn out one ton of steel. This is profitable only where water transport is available, as in the case of Lake Superior, Sweden, and Northern Spain. Where long railway freights would be incurred, as with the rich iron deposits of the Rockies, iron, however abundant, is commercially of little value.

Coke, which is relatively free from sulphur, petroleum, or natural gas, is also largely used in iron smelting.

To extract iron from the ore the latter is smelted, or melted, by intense heat, in blast furnaces with forced draught. The largest furnaces in this country are round Middlesbrough, the centre of the Cleveland district.

Where coal, iron, and limestone occur together, a district is ideally situated for iron smelting. This is the case in the coalfields of the Pennines, in this country, and in the Birmingham district of the Southern Appalachians.

The World's Production of Iron. The total quantity of ore today extracted exceeds 150,000,000 tons, valued at over £42,000,000. The United States turn out over 56,000,000 tons, or over one-third; Germany (with Luxemburg), nearly 30,000,000 tons, or one-fifth; and the United Kingdom, over 15,500,000 tons, or one-tenth. France yields 18,000,000 tons, Spain produces 9,000,000 tons, Russia over 8,000,000 tons, Sweden 6,500,000 tons, and Austria-Hungary 4,500,000 tons. Cuba has an output of nearly 1,500,000 tons.

The world's production of pig iron is about 72,000,000 tons, the United States leading with 29,000,000 tons in 1912, or two-fifths; Germany produces 17,500,000 tons; Great Britain, 8,750,000 tons. Half a century ago the United States produced only half a million tons, and this country only 2,225,000 tons.

Wrought iron, which is malleable, ductile, and very flexible, is made by stirring or "puddling" molten pig iron in contact with the air to burn out the carbon.

Steel. Steel is a form of iron in which the small proportion of carbon required seems to enter into chemical combination with the iron instead of being present as an impurity. Steel is harder and stronger than iron, and finer in grain.

For ordinary purposes steel is made by one of three processes—the Bessemer process, the Siemens-Martin or open-hearth process, and the basic process [see METALS AND MINERALS]. When phosphorus is present in the ore, the basic process is used, lime being introduced to combine with the phosphorus. This discovery allows the Cleveland ores to be made into steel, and has greatly increased the prosperity of Middlesbrough.

The World's Output of Steel. The world's output of steel exceeds 72,000,000 tons, of which over 31,000,000 tons are made in the United States, over 17,000,000 tons in Germany, and nearly 7,000,000 tons in this country. In the United States the steel industry, formerly carried on almost exclusively at Pittsburg, is now extending north to the southern shores of Lakes Erie and Michigan, where the ores of Lake Superior meet the coal of Ohio and Illinois, and to the Birmingham region of the Southern Appalachians.

Fifty years ago, when iron rails were used, only light engines of 25 to 35 tons could be used, and traffic was proportionately slow. Modern engines, running on steel rails, are three or four times as heavy. Steam boilers resist four times more pressure than the old iron ones, so that speed is accelerated while fuel is economised. This has led to an enormous development of railway and steamer traffic, and, generally speaking, to an all-round cheapening of commodities. Great engineering works, such as the Forth Bridge or the bridge across the Zambesi gorge, have been rendered possible. Steel is even replacing timber in the framework of modern buildings, especially in the sky-scrapers of the United States.

Gold and Silver. Gold and silver play an important part in the commerce of the world by serving as the basis of the currency. They have also many uses in the industrial and decorative arts. Both gold and silver are very widely distributed, but many deposits would not pay working expenses. Gold is found in quartz or other rock veins, either pure or in combination. The rock has to be mined, crushed, and chemically treated [see MINING and METALS AND MINERALS]. In many regions gold-bearing rocks have weathered, and gold is carried down by the streams, from whose sediment it can be extracted by washing, the lighter matters draining away and the heavier gold remaining. Roughly done, this process (placer mining) is wasteful, and it is now generally carried out on a large sale by hydraulic apparatus, and the use of mercury, which forms an amalgam with the gold.

GOLD-MINERS AT WORK IN AN UNDERGROUND MINE IN SOUTH AFRICA

The discovery of rich placer deposits in the Californian Sierras in 1848 led to a "gold rush." Similar outbreaks of "gold fever" followed the discoveries of placer gold in Australia in the 'fifties, and in the Klondyke in the 'nineties.

The world's output of gold has been increased in the last half-century by these and other discoveries, and by improved methods of extraction. In 1912 it was estimated at 22,500,000 fine oz., valued at £95,750,000. The Transvaal, where the richest auriferous district is the Rand, near Johannesburg, produced £37,000,000. The United States yielded over £18,000,000, Australia £10,000,000, and Russia £6,000,000. Mexico, Canada, and India rank next. Of the total production three-fifths comes from the British Empire. The import of bullion and specie to this country exceeds £52,000,000, of which South Africa supplies over 70 per cent.

Most of the civilised countries of the world take gold as the standard of value and the basis of the

currency. Owing to its extreme softness, it is mixed with silver, iron, copper, or other alloy to give it sufficient hardness. Gold is also largely used in the decorative arts, and is put to some industrial purposes (photography, dentistry). Gold-leaf is made by beating out a given quantity of gold till its thickness is inappreciable.

Silver. Silver is generally found in combination with other elements, and very commonly with lead. The whole of the Pacific of North America is argentiferous, Mexico, the United States, and Bolivia leading as silver-producing countries. Mexico produces over 70,000,000 oz. The United States exceeds 63,000,000 oz. Canada yields over 31,000,000 oz., or about eight times the output at the beginning of the century. Australia produces nearly 15,000,000 oz. The total output of the world is over 224,000,000 oz., valued at over £28,000,000. The value of silver has fallen rapidly in recent years, being less than 1s. 10d. an ounce in 1902. It has since gradually risen, and stands today at about 2s. 4d. an ounce.

Silver forms part of the currency of gold-standard countries, and the entire currency of many others. It is used in making plate and jewellery, in other decorative arts, in photography [see PHOTOGRAPHY], and also for electro-plating.

Copper. Copper is, after silver, the best conductor of electricity, while it is much cheaper. The demand has therefore increased enormously in recent years. Copper is found either pure, as at Lake Superior and Bolivia, or in ores, the smelting of which presents considerable difficulty, and tends to be carried on at a few noted centres. In the 'sixties, Chile was the main source of the world's copper supply, but it is now surpassed by the United States, which turns out half the world's product of 1,000,000 tons (1912). The output of the United States in 1912 was valued at £41,000,000. The most important deposits, besides those of Lake Superior, are in the Rockies. These are continued in Mexico and in the Andean countries—Chile, Peru, Argentina, Bolivia. In Europe, the chief mines are in the Iberian Peninsula, especially in the Rio Tinto, and in the Harz. Japan is now one of the principal copper-producing countries. The value of copper produced in Australia in 1912 exceeded £3,000,000. The chief smelting centres in this country are at Swansea, Widnes, and Glasgow.

Copper is chiefly used for electrical apparatus, for sheathing ship-plates, and in the manufacture of brass, bronze, and bell-metal. The increasing demand is leading to a rise of prices and rumours of a future copper famine.

Lead. Lead is seldom found pure. It generally occurs in the form of galena, which contains a proportion of silver. In Europe, Spain and Germany are the chief sources of supply. In the New World, lead is found in the Rockies, including Mexico, and in Peru and Chile in South America. The United States produces 30 per cent. of the world's output, which in 1912 amounted to 1,140,000 tons; Australia yields one-tenth of the total. It is in increasing demand for plumbing, roofing, the manufacture of shot and type-metal, and for the manufacture of solder, pewter, Britannia metal, etc. Red and white lead are largely used in the manufacture of paints. The United Kingdom and the United States take more than half of the world's supply of lead, the output of Mexico going to the latter, that of Spain to the former. Great Britain has the largest import and export trade in lead in the world.

Mercury. Mercury, or quicksilver, is a liquid metal, used in making scientific instruments, such as the thermometer and barometer, in gold-mining and medicine. The most famous mines in Europe are those of Almaden, in the Sierra Morena (Spain), Indria, in Carniola (Austria-Hungary), and Northern Italy. In California are the rich mines of New Almaden. Large quantities of mercury are exported from San Francisco to the mines of Mexico and Central and South America. The output at present is 4000 tons, of which Spain supplies nearly 30 per cent, Italy nearly 25 per cent., and Austria-Hungary and the United States each 18 per cent.

Tin and Zinc. Tin, though widely distributed, seldom occurs in paying quantities. The mines of Cornwall, the richest in Europe, no longer supply the demands of the home market. At present the chief sources of supply are the Malay Peninsula, and the islands of Banka and Billiton in the Dutch East Indies. Tin also occurs in Australia, and is exported in some quantity from Tasmania. Bolivia is the chief exporting country in the New World. Tin is chiefly used to coat thin sheets of iron (tinplate), from which tinware is made. The South Wales coalfield is largely engaged in the tinplate trade. Tin is also used in making bronze, pewter, and Britannia metal. Zinc is found in various parts of the United Kingdom, but Prussia and Belgium are the chief sources in Europe. In the United States it occurs in the States of Kansas and Missouri and in Alaska. It is largely used in making galvanised iron, so extensively used for roofs.

Other Metals and Minerals. The other metals of commercial value are aluminium, obtained by electric processes from bauxite and cryolite. Aluminium works are commonly near falls (Niagara, the Swiss valleys, the Falls of Foyers, in Inverness shire), which supply the needful power. For antimony, arsenic, bismuth, chromium, cobalt, manganese, nickel, and platinum, and their uses, see METALS AND MINERALS.

Many other commodities belonging to this class might be mentioned if space permitted. Sulphur, used in making gunpowder and matches, in the vulcanisation of indiarubber, and for many other purposes, is obtained either from volcanic districts or from iron pyrites. Plumbago (graphite, blacklead) is chiefly obtained from Ceylon. Nitrate of soda, a valuable agricultural fertiliser, is worked in the deserts of Northern Chile. Salt is found in many parts, either as rock salt or brine springs. It is also obtained by evaporating sea water.

Marble is the most valuable of many building stones. Lithographic stones are obtained from Bohemia. Kaolin, a decomposed granite which derives its name from the Kaoling Mountains of the Chinese province of Kiang-si, is used in making pottery and paper. It is found in Cornwall, France, Germany, and the United States.

Precious Stones. Nearly the whole of the world's diamond supply comes from South Africa. Brazil supplies only a fraction, and those of inferior quality. Pearls and mother-of-pearl are obtained from the Persian Gulf, Ceylon, the seas round Australia, and Venezuela. Rubies come chiefly from Burma and Siam. Sapphires are exported from Ceylon, Kashmir, Burma, and Queensland. Opals come from Hungary, Mexico, Colorado, New South Wales, and Queensland. Coral, produced by the coral polyp, is fished in various parts of the Mediterranean [see page 3635].

THE DOME UNDER WHICH NAPOLEON LIES

AN ARCHITECTURAL MASTERPIECE—THE DOME OF THE INVALIDES, PARIS

FACING PAGE 6433

The Preparation of Specifications and Estimates. Tenders. Contracts. Supervision of Work. Certificates. Training and Qualifications.

THE EDUCATION OF AN ARCHITECT

THE architect occupies a different position from many other artists, in that he does not, with his own hands, create the works that he produces. In the case of the painter or sculptor, though he may be assisted in certain parts of the work, his artistic creations are due directly to his own craftsmanship. In the case of the architect, though he makes drawings, they are only a means to an end, and the actual achievement is the completed building; and for the carrying out of the building he must call in the assistance of many workmen whose operations in the various building trades have been already described in detail.

His work, moreover, besides having artistic excellence, must usually be designed with a view to giving definite accommodation of some kind or other, and its success will depend not only on its beauty, but in most cases on its utility and convenience. The completion of the work will involve the expenditure of a more or less large sum of money, provided by his client, and for the judicious application of which the architect is responsible. It is necessary, therefore, that he should have a sound knowledge of construction and materials, and at least a fair grasp of business methods.

The Architect Always a Student. The previous chapters have dealt with drawings, which are the principal medium for expressing the architect's intentions; the present deals with some of the more important matters that he has to deal with in his practice, and concludes with some account of an architect's technical education and the present facilities for obtaining it. But it should be pointed out that the architect should remain a student throughout his whole career. New methods of construction are introduced from time to time; new opportunities for studying existing works of merit will be offered as his business takes him to and fro in the country, and possibly abroad, and he will be constantly in a position to acquire new information. A sketchbook and notebook, therefore, should be his constant and life-long companions.

Acquiring Experience. It may be well to point out to the young student, about to enter in practice for himself, that there is much to be learnt besides drawing before a man can become fully qualified to deal with the various problems that inevitably arise when the actual execution of a building begins. Much of this knowledge cannot be taught in any school; much of it may be acquired in the office of a good architect, and it is probably more easily acquired in an office of moderate size than in a very large one; some of it can only be acquired in the school of experience.

The young architect will have to carry out his early work with more labour and trouble than his later work. He will generally have more time at his disposal to give to it and the careful working out of his general and detail drawings, and the preparation of his specification will be well repaid, first, if the work is well done, by the satisfactory result of the completed building; and secondly, by the experience gained and the facility that each carefully studied bit of work tends to give.

Specifications. Next in importance to the architect's drawings, and in a large measure supplementing them, is the *specification*. This is a written description of the work, dealing in detail with the operations of each individual trade employed in the building. It forms, with the drawings, an expression of the architect's instructions to the contractor and his workmen, and is useful for describing materials, methods of work, and so on, which cannot be expressed in the drawings. It should be clear, as concise as possible, and care should be taken to see that it does not contradict the drawings. The young architect should write his own specification, and will learn much in the process, for it describes work in detail, and he must be clear in his own mind as to his intentions before he can properly specify any piece of work.

It should be precise, and all vague terms, like "of good quality," should be avoided, a definite quality or money value being stated wherever possible. It may be useful to take a specification for a similar building as a model, so far as general arrangement of trades, customary phraseology, and the detailing of works in each trade are concerned, but it is dangerous to transfer bodily into a new specification portions of the old, unless it is quite clear that they fully apply to the new work.

In the pressure under which modern work has often to be conducted, it is very usual for the quantity surveyor to write the specification as the quantities are taken off. If this is done, the architect should supply very full notes as to materials, and as much as possible in the way of detail drawings. This method is most successful when the surveyor has worked with the architect on other buildings, and, at any rate, assures that the specification and quantities will agree. The danger is that the surveyor in some matters may not express exactly the architect's intentions, and the architect should carefully read it through after completion. Except in London, it is quite usual for the architect to take out the quantities for his own work, and in such cases he will of necessity also write the specification.

Approximate Estimates. One of the difficulties that confronts the young architect especially is that of providing his client with an estimate of the probable cost of the building. It is often necessary that such an estimate should be given in quite the early days of preparing a design, and that it should be reliable. This is one of the matters which requires experience, but to some extent the experience of others may be of service in some methods of estimating.

For example, with certain types of buildings, the accommodation of which is more or less standardised, it is possible, even without plans, to give a fairly reliable estimate, based on the cost per person. In a hospital, for example, so much per bed, in a church or school, so much per sitting, may be taken as a basis of cost; but even in such rough estimates judgment and experience are necessary in selecting the price which is the basis of the estimate, as there will be very wide range in cost between the cheapest and most expensive buildings of the same class.

Estimate by Cubing. A very usual method is known as *cubing*. This consists in calculating the actual cubical contents of the building. Measurements are taken to the outside of all walls horizontally, and vertically from the top of the footings of the building to half-way up all inclined roofs and to the parapets of flats, allowance being made for any special features rising above this level. Some architects measure the height from the level of the lowest floor; either method is satisfactory provided it is used uniformly for all buildings. The cubical contents being ascertained, the cost of erecting the building, assuming it could be built for one penny per foot cube, is calculated, and finally this sum is multiplied by a figure which experience has proved to be the cost per foot cube of erecting similar buildings. The value of the estimate will depend on this figure being properly fixed, due allowance being given for circumstances, particularly favourable or the reverse; and as the cost per foot cube for different classes of buildings may range between twopence and half-a-crown, or even more, it is easy to see that great care is necessary, and a record should be kept of the cubical contents of all buildings erected by himself, and when possible, by others also.

Caution against Under-estimating. A more exact method, but one involving some expense, is to have the quantities for the general carcase work taken out by the surveyor and priced, and then a percentage added for the finishing trades; this will often give very accurate results. It is, however, fair to say that estimating, however carefully done, has some amount of uncertainty attached to it; for even when quantities are taken out and priced in detail by different builders, it is considered very good estimating if the difference between the highest and lowest tender does not exceed 10 to 15 per cent., and it is by no means unusual for this difference to be as much as 50 per cent., and even more.

The inexperienced architect should resist the temptation of under-estimating; for should his estimate be considerably exceeded by the lowest tender, it is sure to lead to unpleasantness, and possibly to the abandonment of the work.

Quantities. When definite estimates from builders are required, it is generally necessary that *bills of quantities* should be prepared. It was formerly much more the custom than it is now for builders to make their estimates from drawings and specifications, even for important works. Estimates are still prepared in this way for minor works, alterations, and for decorative work in which builders are not put in competition with others, or where not more than three estimates are invited, but for work of importance, in which estimates from several builders are required, quantities are considered essential; and it has been held that instructions to an architect to obtain estimates imply the employment of a surveyor to take out quantities. It is best, however, to obtain definite instructions from the client for his employment, as the payment of his fees is a charge upon him, even though, in the event of a tender being accepted, it is paid by the builder, for the amount of such fees is a "provision" included in the bills. The surveyor's fees are charged by commission on the value of the work, the maximum charge being 2½ per cent., but in plain work, and for work in which there is much repetition, a lower fee may be reasonable, but should be the subject of a definite arrangement. Quantity Surveying is dealt with in detail in a later chapter.

Bills of Quantities. Briefly, *bills of quantities* consist of a summarised statement of the whole quantity of the work in a building, divided into trades. The amount of brickwork, for example, is measured from the drawings and reduced to a definite number of rods, and any special work or labour is dealt with separately. The work in each trade is thus dealt with by the process known as *taking off*—that is, by measuring from the drawings, and *billing*, which is collecting the various items and tabulating them in bills; any special work or features that cannot be dealt with by measuring, such as the setting of a stove in a fireplace, is made the subject of a *provision*—that is, the builder is directed to allow a definite sum for the work, in which case the work done is actually measured or accounted for as daywork on completion, and adjusted with the provision, or is the subject of an *allowance*, in which case the nature of the work is indicated, and the builder inserts a sum which he considers will suffice to meet it. In this case he can neither claim an extra nor be required to account for a surplus. Provision should in either case be made for deducting the full amount if the work is not carried out.

When the bills are completed, a copy is issued to each builder who is to give an estimate, and he charges against each item in the bill the price which his experience suggests as sufficient to cover the cost—in the case above cited, the cost of executing a rod of plain brickwork, which, multiplied by the number of rods, will give the total cost of the plain brickwork. Each item is similarly priced and worked out, and the total cost of all the items in each trade is added up, and finally all the trades are collected and totalled. Some builders, in costing, allow for their profit and management expenses in pricing the details; others price them at prime cost, and add a percentage to the gross total when it is ascertained.

When a tender is accepted, the builder is required to deposit with the architect a copy of the quantities, fully priced out and verified. This may be sealed, and is used as the basis for adjusting the values of any variations due to omissions and extra work upon the completion of the building.

Tenders. When such estimates are required from several builders there are two methods of obtaining them. The first is by public advertisement, the competition being thrown open to any builder who desires the opportunity of carrying out the work. This is the usual method for all work of a public character, and is often used for work done for private clients, especially where it is desired to obtain the lowest possible price for the work. In the second case a limited number of builders known to the architect or to the client are invited to submit tenders—that is, offers to execute the work for a definite sum. When this course is adopted, the builders having been selected, it is held that the builder submitting the lowest tender has a strong claim to receive the contract if the work is carried out. There is not the same claim in advertised work, as it will be necessary, when the builder is not known to architect or client, to investigate his position and business standing, and there may in some cases be good grounds for passing over some of the lower tenders. Whether an invitation is private or public, the client's interests should be protected by inserting in it the following clause: "The owner (or my client) does not bind himself to accept the lowest or any tender, or to pay the cost of preparing any estimate."

It is usual that the tender should include a list of the rates per hour to be charged for the various

tradesmen who are liable to be employed upon the work, for any work that has to be executed as day-work; but no work should be allowed to be charged as daywork that can be properly measured. These prices include builder's profit and usually general foreman's time in supervision.

Contracts. A legal contract is created by a letter from the architect, on his client's instructions, to a builder accepting his tender. After acceptance such a tender cannot be withdrawn, and, on the other hand, if the work is afterwards abandoned, the builder may have a claim for damages. For small works a good contract is created by adding at the close of the specification such a clause as the following: "I undertake to execute the above works under the above conditions for the sum of £——." (Signed) Builder. "Accepted." (Signed) Owner.

The drawings should also be signed, all documents dated, and the contract specification should be stamped with a sixpenny stamp at the time of signing, properly cancelled or stamped at Somerset House within a fortnight.

For important works a set of conditions is required controlling the manner of carrying out the work, and regulating matters of great importance that may arise in connection with its execution. Merely as examples, the following may be cited: time of completion, method and time of payments, death of either party, disputes and arbitration. It sometimes happens that a client desires such conditions to be drawn up by his own solicitor. In that case the builder will naturally require his own solicitor to approve them before he signs the contract, and the architect will also do well to see that his interests are properly guarded. In the large majority of cases, however, it is usual to employ the "Form of Agreement and Schedule of Conditions for Building Contracts" which is issued under the sanction of the Royal Institute of British Architects, in agreement with the Institute of Builders and the National Federation of Building Trade Employers. Separate forms are provided to meet cases (1) where the quantities form part of the contract, (2) where quantities do not form part of the contract. They may be had at the offices of either of the above bodies, and may be procured by non-members as well as members. If this form is used—and it will generally be readily accepted by a builder not belonging to either body—it contains several blanks, which must be properly filled up; and if any conditions, as to payment or other matters dealt with in these conditions, have been inserted in the specification, it is important to see that there is nothing antagonistic between the two.

Supervision of Work. In the case of small works the necessary supervision will fall upon the architect and his staff, and should be of such a character as to ensure that his intentions are being carried out. The amount of actual supervision will depend greatly on the character of the work, and greatly, too, on the character of the builder and his foreman. Where experience proves these to be reliable, it lightens the burden of supervision, though it by no means obviates the necessity for it. Especially in cases where the architect does not know the builder by experience, at least some visits not previously arranged for should be paid. For most buildings of any magnitude a *clerk of works* is appointed, and it is best he should be appointed by and paid through the architect. He is the architect's representative in the job, and should spend his whole time on it. He must be experienced, tactful, sober, and thoroughly trustworthy, or he is worse than useless. A good clerk of works is of great assistance to the architect. He should furnish him with a weekly report of the state of the weather, number of men employed, materials received, drawings received and wanted, and, above all, he must exercise a constant and wise supervision over the work and materials. Any complaint made to the architect by him should be investigated; and it is desirable that the architect should, as far as is possible, support his view if he can reasonably do so, otherwise his authority may be compromised. If in any case his view has been a little bit exacting, he should be told of it privately.

As a rule, it is not desirable that he should do much drawing, though he may have to furnish particulars of work to the architect from time to time, and he should not be allowed to order any works that will mean a variation of the contract. Where a clerk of works is to be employed, the quantities provide that the builder shall furnish him with the necessary office or other accommodation, and with attendance.

Variations. These are a difficulty with which every architect has to cope. It is practically impossible, whatever foresight may be exercised, to design a building—at any rate, one that is large and complicated—without certain matters arising in the course of construction that, upon consideration, could be improved in the manner of executing them, or that may have been overlooked. The greater the care and time devoted to preparing the scheme, the fewer variations of this class will there be, but some are practically inevitable. Further, some conditions that no foresight could have foreseen may arise that will necessitate a variation in the work. This is particularly liable to happen, for instance, in connection with the foundations of a building. Finally, the client may alter his mind about some portion of the work, and require to have it differently carried out. It is usual, therefore, to provide that no variations shall invalidate the contract, and that all such variations shall be adjusted upon the completion of the work. In some cases, especially in the case of clients' variations, it may be possible to obtain from the builder an estimate of the cost of the proposed work before it is ordered, and to submit this and obtain the client's approval; and, wherever possible, this should be done. In most other cases the quantity surveyor must be called in, who measures the work that has been omitted and sets against this the additional work that has been executed. The value of the work is regulated by that of similar work in the priced bill of quantities. Very usually a sum of money—generally a definite percentage on the estimated cost of the work—is provided in the specification and quantities to meet the cost of such variations; and happy is the architect who finds that this provision suffices. More usually variations tend to form a more or less considerable addition to the contract sum, and possibly produce friction with the client, who very naturally requires justification of the necessity for the increased expenditure, which in some cases may be a real source of embarrassment to him.

It is certainly wise, especially for the young architect, to keep a close watch on variations, to avoid them as far as may be, and to be in a position to justify them fully when they are incurred, for a serious claim for variations may very readily result in the loss of a client.

Certificates. The builder is paid usually by instalments during the progress of the work, such payments being made on the architect's certificate. The granting of such certificates is usually regulated by the conditions of contract, a very common arrangement being that the builder is paid at the rate of 80 per cent. of the value of the work done, including joinery and similar work actually delivered on the building, until a sum is held in reserve equal to a settled amount, which is very usually 10 per cent. of the total value of the contract. After such reserve is reached, he is entitled to be paid for the full value of the work. On the satisfactory completion of the contract, part of the retention money is paid over, the balance being held throughout the period for which he is held responsible for making good defects of materials or workmanship. The final balance is only paid on the completion of such work.

The architect must take care to see that each certificate represents as closely as may be the proper proportion of the value of work done, and should avoid over-certifying. On the other hand, he should not keep from the builder money to which he is entitled, except for some special reason. If, for example, the builder had neglected to make good any materials or work to which the architect had objected, this may be a good reason for withholding a certificate otherwise due. In cases where the builder is known to and nominated by the client, the latter should have impressed upon him the importance of his not paying money to the builder except upon the architect's certificate.

Architects' Charges. These are not fixed by statute, and their legal sanction is that of custom. The professional practice as to the charges of architects is set forth in a schedule published by the Royal Institute of British Architects, and to be obtained at their offices. The usual remuneration for an architect's services, with certain exceptions, is a commission of 5 per cent. on the total cost of the work executed Such work is to be calculated as if carried out by a builder with new materials. This covers the necessary preliminary conferences and sketches, approximate estimate if required, the necessary general and detailed drawings and specifications in duplicate, together with one set of tracings of the drawings, and supervision, and examining and passing accounts, but not charges for measuring variations.

It does not cover services connected either with negotiations for the site or for surveying it, or for surveying and making drawings of buildings to be altered, or special services connected with such matters as party walls or rights of light, or for supplying drawings to the landlord, or for drawings supplied to local authorities, or for services connected with litigation and arbitration. For all such matters additional charges—proportionate to the trouble involved, and in some cases depending on the professional standing of the architect—are made. As a rule, out-of-pocket expenses in connection with journeys between the architect's office and the works are chargeable.

For all works of less value than £1000, for special designs for furniture, fittings, and decorative work, and for work involving alterations and additions to buildings, such a commission is not remunerative, and a higher scale depending on the circumstances is usual, but should be a matter of agreement from the beginning.

In the case of partial services where preliminary sketches and interviews only have to be covered, the charge is made in proportion to the trouble and time involved. If complete drawings and specifications are prepared, 2½ per cent. on the estimated cost may be charged; and if tenders have been arranged for and received, 3 per cent. on the lowest tender. There are two methods in general use with regard to the payment of architects. He may be paid at the rate of 5 per cent. on the amount of each certificate as given to the builder, or he may be paid one-half the amount of his commission on the signing of the contract, and the balance by instalments as the work progresses.

Where charges are made by time, the rate depends upon the architect's professional position, and to some extent upon the character of the services. The minimum charge recognised is one of three guineas a day. It is in such matters that the rate of charge that may be made by a beginner differs from the charges made by the man of established reputation. In the case of architects who have acquired a reputation in certain branches of work, charges in proportion to the special value of their services may be made.

It is not desirable that an architect should accept lower remuneration than that recognised as customary, as it amounts to underselling his professional brethren. He is entitled to make any higher charges he thinks fit, provided this is by arrangement with his client, but he could not bring an action to recover such fees and claim the custom of the profession in support of them.

The Architect's Qualifications. The architectural profession is one that calls for special qualifications and training in those who practise it. It is an open profession, the entrance to which is not protected by any system of enforced registration, and opinions in the profession are divided as to the desirability of registration; and, though some steps in this direction have been taken, for the time being, at any rate, it remains open.

A very large proportion of practising architects belong to one or other of the two principal professional bodies—the Royal Institute of British Architects, which is the older and has the larger membership, and the Society of Architects. Each of these bodies has rules governing its own members, relating to education, election to membership, professional conduct, and other matters, but it has no power to enforce them on anyone outside its own body. While membership of one or other body confers a professional status, depending on the position of the society and upon the rank of the member within it, the membership is in no way an indispensable condition of practice.

Both societies now make admission to membership, with few exceptions, dependent upon a thorough and systematic training, as tested by their own examinations. In the R.I.B.A. this was originally introduced as a voluntary test, but has gradually extended its operations, and has been made compulsory; and the training of most architectural students is arranged to lead up to the eventual passing of the examinations of one of the professional bodies. These recognise the successful passing of the examinations of certain schools as exempting their students from the earlier professional examinations.

Architecture has now received university recognition, and the Universities of London, Manchester, and Sheffield each grant a degree of B.A. honours in architecture, the effect of which is to allow the student, after passing the intermediate examination in general subjects, to specialise in architecture

THE GLORIOUS WORK OF INIGO JONES

A MASTERPIECE OF BRITISH ARCHITECTURE—KIRBY HALL, NORTHAMPTONSHIRE

for the final examination. Liverpool University grants a degree of Bachelor of Architecture. In several of the more important towns throughout Great Britain schools are established in which an architectural training is given. In practically all of them the system of instruction, while it aims primarily at preparation for the career of an architect, is so arranged as to allow of students preparing themselves for the Institute or other professional examinations.

Board of Architectural Education. The Council of the R.I.B.A. appoint this Board to deal with the education of students in architecture and to conduct the examinations. The Board recommend: (1) that intending students should in all cases produce evidence of a good general education and of some capacity in drawing; (2) that the course of training should extend over at least four years, of which the first two or three should be spent in an architectural school, and the remainder in an architect's office as pupil, improver, or assistant, the school training being continued during this period, generally by evening work.

The subjects recommended for school training are: (1) building materials; (2) construction, including (*a*) applied mechanics and mathematics in so far as they are necessary to the solution of problems of construction, and (*b*) the practical methods of the building trades; (3) architectural drawing; (4) the study of architectural forms that have been evolved in the architecture of the past out of constructional necessities, and exercises in the design of construction to meet definite problems; (5) the study of the history of architecture in so far as it illustrates and explains the evolution of architecture through constructional material and social conditions.

It is also recommended that the course should include some workshop training, preferably in the form of demonstrations given by craftsmen in the various trades in the actual materials used by the trade, and that visits should be paid to buildings in course of construction, with a view to studying the actual methods of construction on the works. It is recommended that during the period of office training courses of a more advanced character should be continued in these subjects.

The Institute examinations are at present three in number:

The Preliminary. This is to test the student's general knowledge in cases where he has no certificate on leaving school that will be evidence of such training. The fact of having passed the matriculation examination of any university in the British Empire, or certain other examinations, of which a list is given in the R.I.B.A. Calendar, exempts students from sitting in any of the subjects passed at such examination. On passing this examination he is registered as a probationer. This preliminary examination is likely to be discontinued at an early date, and students will be required to produce satisfactory evidence of a good general education in the form of a certificate of having already passed some recognised examination in general knowledge before being registered.

The Intermediate. This examination is open to a probationer of seventeen years of age, who must submit eight sheets of drawings as testimonies of the course of study he has pursued, and, if these are approved, is admitted to the examination. This corresponds to a standard such as would be obtained by a satisfactory student who had taken a two years' or three years' course at one of the universities or other schools of architecture, and the Institute recommend students in all cases where such courses are available to take them. In the case of students who have obtained satisfactory certificates at one of the universities, and at certain other schools of which a list is given in the R.I.B.A. Calendar, exemption is granted from the intermediate examination; and such students, and those who pass the examination, are registered as students of the Institute.

The Final. This examination is open to students of twenty-one years of age. Every student, with his application, is required to submit four accepted problems in design chosen from alternative problems set by the Board of Architectural Education, or other designs which may be accepted in lieu of them, together with a thesis. The examination is divided into two parts: (1) design of a building of moderate dimensions; (2) papers on construction, hygiene, building materials.

University Training. Often a university degree is first obtained before beginning the professional training. This can best be obtained in a properly organised school, and there are undoubted advantages in selecting one, where circumstances permit of a university standing.

In London the University School of Architecture at University College has been formed by amalgamating the school formerly existing at that college with the school formerly at King's College, and provides two-year and three-year courses specially adapted for students intending to take the college certificate giving exemption from the R.I.B.A. intermediate or the university degree respectively. In addition to the subjects already detailed, the course allows of students attending for a portion of their time at the Slade School for the practice of drawing from the figure and modelling, while special courses in archæology, or engineering, or in other faculties can be arranged for. Advanced work is also provided for by a course in academic design and by a course in town-planning. A complete set of demonstrations in the various building crafts is also arranged. Courses generally similar in scope are provided by the Universities of Liverpool, Manchester, and Sheffield.

Courses of Training in London. Of schools not of university standing the most important probably is that of the Architectural Association in London, which provides both day and evening instruction on the lines recommended by the Board of Architectural Education, and whose students, on satisfactorily passing a three-years' course, obtain exemption from the R.I.B.A. intermediate. Other facilities for more or less complete courses of training in London include the Architectural School of the Royal Academy of Arts (design only), the Royal College of Art, the L.C.C. School of Building, the Polytechnic, Regent Street, and other centres.

Courses in the Provinces. Outside London the facilities for training are much more widely diffused than was the case a few years ago; and a large number of the more important towns throughout Great Britain can offer some definite courses of instruction to intending students, and in some cases these are very complete and efficient. Among them may be mentioned the Technical College, Aberdeen, Birmingham Municipal School of Art, Glasgow School of Architecture, and the Leeds School of Art.

R. ELSEY SMITH

Loss Caused by Insect Pests, and how it is Combated. The Chief Pests and the Fruits they Attack. Spraying Methods and Formulæ.

ENEMIES OF THE FRUIT GROWER

With the increase in the amount of fruit grown in the country, the injurious insects and fungi have likewise increased at an alarming rate. It is, after all, only the natural sequence to the transformation that has been made in our countryside; as long as fruit is massed together in certain districts, thus providing an ample and easy living for these noxious pests, so long will they continue to thrive.

In the early days a farmer or market gardener in a certain locality would find that the small portion of land that he had under fruit cultivation was very profitable, and, naturally concluding that his land must be suitable for the production of fruit, planted more. His neighbours, seeing that he was making more money out of growing fruit than they were out of ordinary farm or garden crops, would follow his example, until the whole district gradually became entirely given over to fruit cultivation.

In those days many of the pests which now trouble the fruit-grower and lessen his profits were unknown, but as time has advanced they have become a real menace and a danger that has to be reckoned with—how great may be gathered from the fact that it has been estimated that in the United States alone the loss caused by these little enemies of the fruit-grower amounts to no less a sum than between £70,000,000 and £80,000,000 annually. In this chapter it is intended to deal with the subject in such a manner as to be of practical service to the smallholder, market gardener, and allotment holder.

As these troubles arose, it became very apparent to the practical man that something must be done, and done quickly, or else the fruit-grower would have to go out of business altogether. Men began to think and watch and study; they found that these insects existed in other forms: they found that they change their form, and that, though they might do the damage at one period of their lives, there were other periods when it was easier to attack them. This resulted in the fact being forced upon students that the life-history of these insects must be studied and worked out in order to ascertain at which period of their existence they could most easily and effectually be eradicated.

Insect Transformation. The majority of these insect pests undergo a complete change of form and appearance at different times of their life. They exist as (1) the egg; (2) the caterpillar, which is termed the larva; (3) the chrysalis, or pupa; (4) the adult, or perfect insect. In the majority of cases it is in the caterpillar stage that they do the most harm, sometimes by gnawing the roots, in other cases by attacking the fruit-buds; others enter and eat the fruit, and some devour the foliage.

Nature, when left to herself and not interfered with by man, regulates the damage done by providing natural enemies to the destroyer, one species of insect living on another, and thus maintaining the balance. It will be readily understood that insects cannot increase beyond the supply of food on which they live. In the case of some their food is vegetation; for others it is other insects.

When an insect pest has occurred in wild vegetation, there has generally appeared another insect which is parasitic on the first—that is, lives on it. If, on the other hand, the pest has not been interfered with by a parasite, it increases at a very rapid rate, and soon destroys the particular form of vegetation which is its food before the plant has seeded, thus starving itself by preventing a further growth of that variety of plant in the same neighbourhood in another season.

Let us suppose, for instance, that a field of clover has been destroyed by a certain species of insect; as the plant has been destroyed before the seed has ripened and fallen there will be no crop for the insect to feed on another year. Under modern conditions man now steps in and provides seed from another district, thereby providing food for the insects, so that, instead of being starved to death, they are able to multiply.

Under Nature's conditions, when the pest first began its depredations a parasitic insect would have been attracted to the neighbourhood because of the food supply, and have largely, if not entirely, destroyed the original insect pest, and in turn have starved itself because it had destroyed its own food supply.

Though there are certain natural enemies of the insects that cause the fruit-grower so much loss, and though these do render him a certain amount of assistance, they cannot be relied on to any extent, because the fruit-grower himself has destroyed the balance of things by providing food for his enemies to an abnormal and unnatural extent, without at the same time increasing the number of parasites. From this it will be seen that too much importance must not be placed on the assistance of the natural enemies. Nature's conditions having been interfered with, it becomes necessary to adopt artificial measures of protecting the trees from the pests.

It is of great importance to remember that the stronger and better the tree, the better able is it to resist the attacks of insect pests, and also of fungus disease, which is another form of trouble that affects fruit trees.

Remedial Measures. There are two distinct forms of remedies—*insecticides*, or insect killers; and *fungicides*, for destroying and preventing fungous growths. The methods of dealing with these enemies of the fruit-grower may be divided into four classes: (1) Contact remedies, which destroy by actual contact with the pest; (2) toxic remedies, which act by poisoning its food; (3) gas treatment, by gases or fumes given off by certain chemicals; (4) mechanical and preventive measures.

To the first class belong all the fungicides and those insecticides used against sucking insects, the principal of which are nicotine, soft-soap, lime, sulphur, and salt washes, Bordeaux mixture, and paraffin emulsion. The formulæ for the preparation of these is given on page 5450.

In the second class are those insecticides used to destroy chewing or eating insects. Among these are hellebore powder and arsenate of lead.

The third class includes carbon bisulphide,

which is injected into the soil by means of an injector [51], and such proprietory preparations as Vaporite which are dug into the ground.

The fourth class consists of such devices as grease-banding of trees, and very bright lights used at night to attract moths. The one illustrated [52] has a pan surrounding the light underneath; this contains water, which has a small quantity of paraffin floating on the surface. The bright light attracts the moths, their wings get singed, they fall into the pan underneath, and are speedily overcome by the fumes of the paraffin.

It will not be possible to mention all the insect attacks to which a fruit plantation is liable, but those described under the headings of the different fruits will be found to be the chief offenders and those against which it is most necessary to wage unceasing warfare.

APPLE FOES

Codling Moth. One of the most troublesome of the insects attacking the apple is the Codling or Codlin Moth [see page 4726]. This moth lays its little, transparent eggs in the flowers or on the newly formed fruit, where it looks like a tiny drop of dew; usually only one egg is laid on each blossom. When the caterpillar hatches out of the egg it eats its way into the inside of the apple, tunnelling through to the core, and the result is the maggoty apple. The grubs are somewhat deceptive, being sometimes creamy white and sometimes deep pink. Later they leave the fruit, and at some sheltered spot on the tree, such as under old bark, they spin a silken cocoon, where they remain sometimes the whole winter, afterwards changing to small brown pupæ and emerging as moths in the spring. As moths they are at rest in the day, and fly about in the evening and at night, and are thus among those likely to be attracted by a bright light, and caught with such devices as the lamp already mentioned. Another means of catching a number of these pests is to tie a band of hay or sacking round the trunk of the tree, near the ground. The grubs will, many of them, spin their cocoons under its shelter, and these can be collected in the winter. The most satisfactory remedy, however, and one that should not be omitted, whatever other may be tried, is to spray thoroughly with arsenate of lead paste directly the blossom has fallen, not later than a week or ten days after the flowers drop. The grub, on hatching out, will then feed on poison, and die. The spraying must be done very thoroughly to be successful, otherwise it is waste of time and money.

Winter Moth. Another troublesome little grub is the larva of the Winter Moth [see page 4726], which attacks the young sappy buds in the spring and feeds on the young shoots and leaves, and afterwards on the young fruit. It is one of the varieties of "loopers," so called from their method of locomotion. They bring their hind legs up to their front ones, forming a loop with their body; then, stretching themselves at full length, they alight on their front legs and repeat the operation. This winter moth grub is yellowish-green, with pale green lines running the length of its body on either side. It reaches an inch or more when it is fully grown. Towards the end of May the grubs presumably fall to the ground. Here they form a silken cocoon, within which they change to small brown pupæ.

About October they usually emerge as moths, the males generally preceding the females. The males have full wings—that is, two pairs. When expanded they are about an inch and a quarter across. The distinctive feature of the females is that they have scarcely any wings at all, and are certainly quite unable to fly. The colour is brown or greyish-brown. The eggs are laid around buds, in the little crevices of twigs, are pale green—afterwards changing to brick colour—and have a very thick shell.

Although it is the grub that does the actual damage, it is in the moth stage that we have the best chance of checking this pest. The female, being unable to fly, crawls up the trunks of the trees to lay its eggs. It thus provides an opportunity for its destruction. This is done by arranging some means of trapping it as it ascends the tree.

There are three methods in use—the first is a tin collar which has a sticky substance smeared on the underneath side. This fits closely round the trunk of the tree as illustrated [53]. The second method is a piece of parchment or grease-proof paper [see page 4730] tied round the trunk of the tree [54 and 55], on which a similar substance is smeared; and the third is a piece of sacking about twelve inches wide tied tightly round the bottom and again about six inches up, and then folded back, forming a double band, and open at the bottom but closed at the top [53B]. In the first two cases the moth gets stuck on the grease and is thus stopped, and in the latter case it crawls up the inner piece of sacking and reaches the folded-over top and can get no farther. In the case of this pest we can also combat it in the grub stage by spraying the trees with arsenate of lead paste when the young caterpillars are attacking the buds and leaves.

The Mottled Umber Moth [see page 4726] and March Moth, which also attack apple-trees, are very similar, and the treatment of these is the same as for the Winter Moth.

Lackey Moth. About May there may be noticed on the apple-trees silken webs woven about the leaves, and enclosing within each web, which resembles a tent [see page 4726], numerous small dark caterpillars. If these are watched it will be seen that the webs or tents are gradually enlarged until they may be as long as ten or twelve inches, the caterpillars themselves growing brilliant in colour as they grow in size, becoming bluish-grey with three orange stripes down each side. A white line appears down the back, with a black line on each side of it. They now begin to leave their tents in the daytime, returning to them at night, and when fully grown they break up their colonies altogether and wander about the foliage. These are the larvæ of the Lackey Moth, and they do much damage to both foliage and buds.

About June or July they change to dark brown pupæ, housed in loose silken cocoons, either singly or in groups. There emerge in a few weeks reddish-brown moths about an inch or rather more in wing expanse, having two transverse lines across the front wings. These moths lay their eggs in July or August in a very peculiar and noticeable manner. They can readily be seen by the careful observer, gummed closely together in bands around the twigs, sometimes as many as 200 eggs in a band, sometimes only about 50. The appearance of these bands will be seen from 56.

A good way of appreciably lessening the attack for another year is to cut away the small twigs where these eggs are and burn them. As the tents of larvæ are easily seen, it is a good plan to burn these by means of a torch. This is most effectively accomplished as they are in the trees, as any attempt to remove them will allow of the escape of many of the

caterpillars. If the best results are to be achieved, this operation should be carried out in the early morning before they have left the webs, or in the evening after they have returned. Spraying with arsenate of lead is also helpful, as in the case of the other pests already mentioned, as this poisons their food.

Woolly Aphis. The presence of Woolly Aphis is indicated by patches of a white, cottony substance in the crevices of the trees and around the roots. If these are examined, there will be found tiny insects resembling the well-known "greenfly," but of a dirty white colour and slightly larger. This is one of the most troublesome of the pests that attack the apple, and many growers have been disappointed with the results after spraying the trees most vigorously. If they had only known the reason, they would have realised that the unsatisfactory result was due to the fact that they had not got to the root of the trouble, which in this case happens to be at the root of the tree, under which the insect begins its attack beneath the ground. For this reason it is sometimes spoken of as "root louse." Here it is more or less protected owing to the difficulty of getting to the under side of the roots with a spraying fluid, but unless the pest is killed below the ground it is of little use to get rid of those on the tree, as their places will speedily be taken by those from underneath. This is one of the cases, then, where a gas treatment will be most beneficial, by exterminating the pest under the soil. It will be found that if carbon bisulphide is injected into the ground it will give off a gas that will permeate the soil and kill the insects. The upper part of the tree can then be sprayed with a paraffin emulsion wash.

51. AN INJECTOR

The damage done by woolly aphis is two-fold—it causes galls or swellings on the root, and also sucks the sap, which is the vitality of the tree, often causing a black, cankerous appearance, which spreads and kills the limb of the tree. Very often young trees refuse to develop, however much the fruit-grower may try to encourage them, and when dug up it will be found that woolly aphis is the cause, as sometimes there is no indication above ground when there may be serious trouble underneath.

Unfortunately, the insects attacking the apple are too numerous for a description of all to be given here. Some of the more common are:

LEPIDOPTERA (moths): Vapourer Moth, the Tortrices, Leaf Moths.

COLEOPTERA (beetles): Apple-blossom Weevil, Blossom Beetles, the Chafers.

HYMENOPTERA (saw-flies and wasps): Apple Saw-fly, Wasps, Leaf-cutting Bee.

HEMIPTERA (aphides and scales): Apple Sucker, Cuckoo-spit Insect, various families of Aphis.

52. LAMP FOR ATTRACTING MOTHS

PLUM FOES

The two great insect enemies of the plum are Winter Moth and the Plum Aphis. Winter Moth has already been described.

The Plum Aphis. The Plum Aphis causes the leaves to curl and sucks the life from the tree. Unfortunately, this pest seems to have increased to an alarming extent during the last few years. The aphides reproduce very rapidly, and in the course of a few days the leaves of a healthy tree may roll up and die, and if they are examined will be found covered with these aphides. Strange to say, the leaves, though dead, will often hang on the tree, causing it to have a burnt appearance. No sooner do the leaves begin to shrivel than the fruitlets begin to fall, and in the case of bad attacks, although there may have been a good show of blossom, by the end of June there will be scarcely any leaves or fruitlets on a tree.

If this pest is attacked in the early stages it can be kept within bounds so that it will do no great amount of damage. This is one of the particular instances in which a strong wash late in the winter has been found very beneficial.

The first females of the year are hatched from shiny black eggs that have been laid in the autumn. These females being viviparous—that is, producing living young—and the young having the same ability, they increase extremely rapidly throughout the summer. The first females, therefore, should be killed before they begin to reproduce. Moreover, as they have the habit of curling the leaves, it is almost impossible to touch them with a spray when they are sheltered under the leaves.

Winter Washes. It is supposed, from the beneficial results obtained from experiments conducted in winter spraying, that a heavy winter wash such as lime, sulphur, and salt, although it will not kill the egg, yet, having covered the tree, ensures that the food supply of the young aphides is cut off. The result is that they cannot live if they hatch out.

Winter washes are always advisable, not only for plums, but for other fruit trees, as they do considerable service in burning off lichens and mosses, thus leaving a clean bark, unfavourable for the harbouring of insect pests and eggs. Lime, sulphur, and salt boiled make, perhaps, a better wash than any other, as it adheres evenly to the tree, and has not that tendency to peel off in patches that a lime, sulphur, and waterglass wash has. This difference is clearly shown in the illustration of the three twigs [57].

It will be noticed in 58 that the lime, sulphur, and salt wash with which the damson orchard has been sprayed still remains evenly on the trees though they are breaking out into leaf. There are a number of commercial preparations of lime and sulphur on the market, but, owing to the necessity of straining them, they do not give the tree such a white appearance as the home-made article, which is boiled on the spot and has not been strained, other than by the strainers in the pumps as it passes through.

A very great advantage of the whitening of the trees lies in the fact that the operator can see

where he has been, and is therefore less likely to miss any part, and, also, if a careless man is doing it, slipshod work is at once apparent to his employer as well as to himself.

Red Spider. The Red Spider is one of the oldest of the pests known to the fruit-grower, and an indication of its presence on fruit-trees is that the leaves lose their brightness, gradually their

53. DEFENCE AGAINST WINTER AND MARCH MOTHS
A. tin collar; B. double piece of sacking; C. parchment or grease-proof paper

colour disappears, and they fall off. The fruit does not develop, and drops. The spider sucks the sap, and thus takes the vitality of the tree. The eggs of this pest are small, globular, red bodies, and will be noticed in the winter-time so thick on certain trees as to make the twigs look quite red.

These eggs are often mistaken for small Beetle Mites that are very often found in large quantities on the trees, and are known as *Oribatidæ*. In fact, it is almost impossible to distinguish between them with the naked eye, but every intelligent and seriously minded fruit-grower, smallholder, or allotment-holder will have his magnifying-glass or lens in his pocket. Special attention should be paid to this, as it is generally accepted that these mites at least are neutral, if not beneficial, whereas the red spider is most distinctly injurious. It may be well to mention that the mites will remain perfectly at rest when cold, and cannot be observed to move, even under the magnifying-glass, until brought into warmth. Their eggs are also very similar to the red spider, being deposited in masses on the tree-trunks, giving them the appearance of having rust or brick-dust on the bark.

Other insects attacking plum-trees are:

LEPIDOPTERA: Plum-fruit Moth, Plum Tortrix, Vapourer Moth, Codling Moth.

COLEOPTERA: Shot Borer Beetle, Plum Weevil, Green Leaf Weevil.

HYMENOPTERA: Plum leaf, Plum-fruit Saw-flies.

HEMIPTERA: Hop-Damson Aphis, Mussel-scale, Oyster-shell Bark Louse.

CHERRY-TREE PESTS

There is nothing that attacks cherries that need be singled out, as all of the following are equally troublesome:

LEPIDOPTERA: Winter Moth, Mottled Umber Moth, Lackey Moth, Cherry and Plum Tree Borer.

COLEOPTERA: The Chafers, Green Leaf Weevil, Oblong Leaf Weevil.

DIPTERA: Cherry-fruit Fly.

HYMONOPTERA: Cherry Slug Worm.

HEMIPTERA: Cuckoo Spit, Cherry Black Fly.

PEAR-TREE PESTS

The insects that trouble the pear-tree are similar to those mentioned:

LEPIDOPTERA: Winter Moth, Mottled Umber Moth, Lackey Moth, Codling Moth, Tortrix Moths.

COLEOPTERA: Apple-blossom Weevil, Fruit Bark Beetle, Leaf Weevils.

DIPTERA: Midges.

HYMENOPTERA: Apple Saw-fly, Pear Slug Worm.

HEMIPTERA: Woolly Aphis.

Social Pear Saw-fly. It may be well to draw attention to the Social Pear Saw-fly, as it makes a tent similar to that of the Lackey Moth, though the webs are usually much wider. The female saw-fly lays from thirty to sixty eggs early in July under the surface of the leaves. The larvæ hatch out in about a week, and when first hatched are straw coloured, changing afterwards to orange-yellow, having a longitudinal pale brown stripe on either side; the head is black and polished, and there are two black spots on the second segment. A peculiarity of this insect is that the pupæ will very often live in the ground through another season. This accounts for the fact, which has sometimes puzzled entomologists, that the saw-fly, plentiful one year, will disappear the next year, and reappear in numbers during the following year. After an attack by this pest it is well to give an application of gas-lime, taking care that it is well worked into the ground with a pronged hoe. Gas-lime should always be left exposed to the air for at least two months before applying it to the land, and even then it is well not to hoe it in for another two months.

STRAWBERRY FOES

Garden Swift Moth. Considerable damage is sometimes done to strawberries by the Garden Swift Moth, which, in the larva state, lives in the soil, and feeds on the roots of the plants. This moth has a flight peculiar to itself, darting swiftly backwards and forwards. Hence its name. It is a noticeable fact that the majority of moths take great care and, apparently, some amount of trouble to lay their eggs quite close to the food the larvæ particularly favour, so that the supply

54. PUTTING ON BANDS

55. APPLYING GREASE

is ready for them as soon as they are hatched, without any search being necessary on their part. In the case of this moth, however, the female just drops the eggs as it flies about at dusk, and the caterpillars, when they hatch out, enter the ground, and have to find their way to some palatable root. Fortunate indeed are those who find themselves near or in the midst of a strawberry bed,

but not so fortunate is the fruit grower, who soon discovers that his strawberry plants are suffering.

The eggs are laid in late June or July, and hatch out in little over a week and the larvæ feed all the winter until about April or May, when they pupate in the soil as brown, ridged pupæ, emerging as moths during May and June. The larvæ are dull white with brown heads, and have four hairs on each segment, and grow to 1½in. in length. They wriggle backwards very quickly when touched. As with most pests that feed in the ground, some gas treatment is of the most use in getting rid of them. Kainite, muriate of potash, gas-lime, or Vaporite are all beneficial. It is quite worth while to let fowls run over the ground, as they pick out a considerable number of the grubs.

56, BAND OF EGGS OF LACKEY MOTH

Root Eelworm. Strawberries attacked by this pest rot away from the root upwards. The eelworms—which are very tiny, about a twentieth of an inch long—infest the roots, and gradually the plant also near the surface of the soil. Reproducing with very great rapidity, they quickly cause it to rot and die, when they then spread themselves out over the surrounding soil, and attack other plants. This accounts for the fact that the strawberries seem to decay in patches. The remedies usually advocated are artificial manures to strengthen the plants sulphate of potash, or kainite. Eelworms sometimes infest stable manure and may be thus introduced to the strawberry-beds.

Ground Beetles. There are four species of beetles that damage strawberries, but all are similar in their habits. They are nocturnal, and rest in the day. They are principally found in June and July, and lay their eggs in the soil. The fact that the larvæ feed partly on slugs and insects may seem to indicate that they are beneficial rather than harmful, but as they make the strawberry fruit their chief delicacy, and feed off the ripening fruit to a very considerable extent, they must be looked upon as enemies, and not as friends, where there is a strawberry-bed to consider. They belong to the family called *Carabidæ*, which, speaking generally, are beneficial. The larvæ have three pairs of legs, hard, plated backs, large biting jaws, and on the last segment two pointed horns, with a fleshy kind of leg below. A good plan for catching the beetles is to sink pots in the ground containing meat, or sugar-and-water. Moles and hedgehogs will eat them.

Crane-flies or Daddy-longlegs. The larvæ of the Daddy-longlegs [see pages 4726–27], commonly spoken of as "leather-jackets," often attack and eat the roots of freshly planted strawberries. The appearance of these soft, dirty grey grubs is well known, but many are not familiar with their life history. The Daddy-longlegs deposit their minute black eggs in the ground, generally in grassland. From these hatch the legless maggots, which lie in the soil in a dormant state during the winter, rousing themselves in the spring to do immense damage to many crops. They vary considerably in size, sometimes attaining 1½ in. or more in length when fully grown. They are voracious feeders, and gnaw through fleshy roots, and are particularly destructive in grass and clover. They attack raspberries and loganberries as well as strawberries.

Sometimes a field of strawberries has to be replanted from this cause alone. Such was the case in Cambridgeshire a year or two ago. When fully grown they change to pupæ, in which state they do not need to feed. As soon as the hot weather begins to arrive the pupæ force themselves partly out of the ground, sticking out half of the body; their skin bursts open, and the fly emerges. They are often to be seen in the early morning of a summer day forcing themselves up through the lawns and grass meadows.

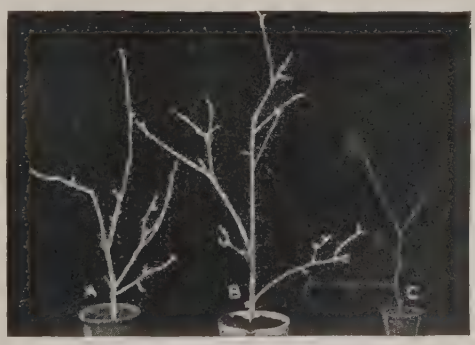
When the "leather-jackets" are in grassland the best remedy is to roll it with a heavy ring-roller in the early morning, as the pupæ are pushing their way through the ground, to crush them.

It is always best, when ploughing up old grassland, to give it a dressing with gas-lime before sowing it with any other crop or planting it with fruit, but in the case of their presence among young strawberry plants the best cure is to keep hoeing the ground, allowing fowls and young ducks to follow the men at work, when it will be noticed that they will readily devour the grubs or maggots.

Slugs and Snails. While considering insects which attack strawberries, slugs and snails must not be forgotten. These are—at any rate, to the novice—the most easily recognised of all. The best remedy is to allow ducks to wander over the strawberry beds, particularly in the early morning and in damp weather, when it will be seen that they devour them eagerly.

It may be well to point out that slugs do their damage when the fruit is ripening and the plants have been strawed, making hoeing impossible. The case is therefore different from that of the "leather-jackets." For the latter, fowls were suggested, but they will not do for the slugs, as they would be apt to scratch away the straw from the berries, but ducks do not scratch.

In the case of snails, they have a natural enemy,



57 THE EFFECT OF SPRAYING

A. with lime, sulphur, and salt; B. with lime, sulphur, and waterglass (note the wash flaking off); C. not sprayed

the common song-thrush; and, although the thrush will itself do a certain amount of damage to the crops, it more than compensates for this by the service it renders. It will take the snail in its beak, knock it again and again on a stone until the shell is broken, and then eat it with apparent relish. In this way one thrush will devour great numbers of snails.

Other insect pests of the strawberry are:

LEPIDOPTERA: Heart and Dart Moth, Strawberry-leaf Button Moth.

COLEOPTERA: Strawberry Weevil, Strawberry-fruit Weevil, Strawberry-leaf Beetle, the Chafers.

HEMIPTERA: Strawberry Aphis.

VERMES: Strawberry Eelworm (commonly known as cauliflower disease).

Strawberry Mildew. One of the greatest troubles that the strawberry-grower has to contend with is the strawberry mildew. This is a fungous disease, and has therefore no connection with any insect pest which may be present. The mildew attacks not only the foliage, but also the fruit.

The uninitiated is apt to think that it is of little importance, as it does not hinder the development of the fruit, but when he wishes to market the fruit he will learn to his cost that his crop is valueless, for it will have lost its sweetness and have a flat, insipid taste. Unscrupulous growers have been known to wash their strawberries affected with this disease in order to obtain a sale of them, but even then they present a dull, lifeless appearance, and are of no value whatever for eating or preserving.

When this fungus attacks the leaves they curl upwards, and will be seen to be covered with a white, powdery mildew which is the summer stage of the disease; this in time spreads to the fruit itself. When a garden has been attacked, the leaves should all be cut off and burned, and in the following spring, when the plants begin to grow again, they should be sprayed with sulphide of potassium or dry lime and sulphur. This latter should be dusted on to the plants, care being taken to see that the under side of the leaves is sprayed in the early morning, when the air is generally still and the leaves are saturated with dew.

RASPBERRY PESTS

The Raspberry Beetle. Everyone has come across the maggoty raspberry. The percentage of berries containing one or more of these little white grubs is very high, and raspberries are spoilt as a dessert fruit by this cause alone. Everyone, however, does not know that in the adult form these maggots are small brown beetles, about one-seventh of an inch long. They may be seen in large numbers about May and June, when the plants are in blossom, flying hither and thither with great rapidity when the sun is shining. The method that these beetles follow is to lay an egg, generally only one, in the heart of the flower. From this hatches out a little white grub within the ripening fruit. It therefore finds itself right in the midst of its food supply, and begins to feed on the berry.

It has sometimes been supposed, as two or more grubs may be found in one raspberry, that the beetle must lay more than one egg in a blossom. This is not so, however, and the fact that several grubs are found is probably accounted for by the fact that more than one beetle will visit the same bloom. Another explanation may be that the grubs crawl out of one berry and pass to another. It might be supposed that the maggots, being in the fruit and the fruit being practically all picked each season, would in that way automatically become exterminated. Unfortunately, large numbers of the grubs leave the berries which have been their host while in the egg stage, and which have perhaps not developed properly in consequence of their attack, and in travelling to another more perfect fruit fall to the ground. In this way many escape through not being picked with the fruit.

An opportunity for their destruction, however, is presented by the fact that they reach the ground, as lime and soot can be hoed into the soil and fowls may be allowed to run at will among the canes. This matter should be attended to directly the fruit has been gathered.

The grubs pupate, for the most part, in the ground, emerging in the following spring as the adult beetles. The beetles themselves have been found in the soil in Cambridgeshire as early as February 14, and in April in quite large numbers on the surface of the soil round the bottoms of the canes, although it had previously been supposed that they did not emerge from the pupæ until the beginning of May.

This seems at first sight to be contrary to Nature's usual way. The canes are not even in leaf, and certainly there are no blossoms in which the beetles can lay their eggs. Experts are still trying to find out what these very early beetles feed on, as the other plants they favour are the loganberry and buttercup, which are also dormant. There is an opportunity, therefore, for any intelligent grower to do a little research work on his own account, and perhaps make a valuable addition to what is already known of the life-history of this troublesome pest. It seems likely that there is still some habit undiscovered, as, in spite of all precautions, it appears to hold its own and is difficult to eradicate.

Spraying the canes with arsenate of lead paste when the beetles are flying about is thought to act as a deterrent to the beetles laying their eggs on the blossoms or plants. Injecting carbon bisulphide into the soil has been tried to kill the pupæ, but the damage resulting to the young spawn of the canes made the remedy worse than the disease.

The methods adopted for working out the life-history of insects varies somewhat. The cage illustrated [59] was, when photographed, actually in use among the raspberry canes for investigation work concerning the particular insect pest described above. It is made with a zinc top, finely perforated to admit rain and air; the side panels are of glass in the upper part to admit light, and finely perforated zinc in the lower part to secure a constant circulation of air. The beetles are thus enclosed so that they may be under constant observation, yet at the same time they are living under their natural conditions. In this manner the observer avoids the risk of any departure from their usual habits such as might happen if the beetles were removed.

Raspberry Moth. Another enemy of the raspberry, that in some districts does as much damage as the raspberry beetle, is the Raspberry Moth. It is sometimes known as the Red Raspberry Grub, or Stem Bud Caterpillar, from the fact that it is red in colour, and attacks the buds or terminal shoots, causing them to wither away and die. Very often, when a shoot has been attacked, Nature makes an effort to repair the loss, and two new shoots will be sent out where the previous one has died. This weakens the canes, and thereby reduces the crop.

This moth is one of the smaller moths, measuring only about $\frac{1}{4}$ in. in length; it is brown in colour with yellow spots. It may be termed a hard worker, as it flies both by day and by night at the end of May and through June. The eggs are laid on the blossoms. When they hatch out, the larvæ, which are small and pale in colour, enter the core or berry, where they remain for some little time, but they do no harm and the fruit is undamaged. Here may be noticed a peculiar or rather unusual habit. It is

not during the season that they are hatched that these grubs do their damage; they leave the fruit before it is ripe, fall or lower themselves to the ground, spin a cocoon in some sheltered spot, and there pass the whole of the winter; in the following spring they awake to new life, and feed on the young buds. They now change, first to pink and then to red, and not only make the buds their food, but

58. DAMSON ORCHARD WINTER-SPRAYED WITH LIME, SULPHUR, AND SALT

tunnel into the pith of the shoots, and finally pupate either in the pith of the cane or in the shoot. The pupa is reddish-yellow and pale pink underneath, being about ½ in. long. After three weeks or more the pupa pushes up out of its crevice, and the moth emerges.

In seeking to eradicate this pest the fact that they pass the winter as larvæ must be borne in mind. The fowls will again render us valuable service, as will also lime and soot hoed into the ground at the base of the canes. Care should always be taken, when the canes are pruned in the early winter, to burn at once all that is cut out, thus securing the destruction of any grubs that may have settled down to hibernate in the canes.

Where raspberries are grown only on a small scale, as in gardens, allotments, or even, perhaps, small holdings, it may be found possible to paint the lower part of the canes with soft-soap. This should be done in March, to catch the larvæ as they ascend the canes on their way to the buds. It will be seen, however, that this would hardly be practicable on a large scale. If a strict watch were kept to find out the time that these larvæ began feeding, the canes might be sprayed with arsenate of lead paste, which would kill them as soon as they began to eat the buds.

Chafers. The Cock Chafer, the Rose Chafer or Beetle, and the Small or Summer Chafer, all well known as devouring the foliage of many trees and plants, will often attack raspberries. As adults they eat the leaves and blossoms, but do still more damage as larvæ, in which state they live in the ground and feed on the roots for two or three years in the case of the Cock Chafer and Rose Chafer, and for one or two years in the case of the Small Chafer.

The Cock Chafer has a black head, reddish-brown wings, and brown, hairy legs. It is often 1 in. in length, is a strong, heavy beetle, and may be noticed in May or June flying about at night, and is distinguishable at some little distance by the loud humming noise characteristic of its flight. The female buries her eggs in the ground; the grubs are thick with a swollen piece at the tail end, dirty white in colour, with six jointed legs in front. They move very slowly, and appear scarcely alive when taken out of the ground, but when in their native element they move quite freely, and do immense damage by gnawing the roots, sometimes working away at the same group until the canes are completely killed. At the end of three years they make a cell, and change into pale brown papæ.

The other allied species are similar in habits. The Rose Chafer is a very pretty beetle of a brilliant green with a golden sheen, and is about two-thirds of an inch long. The Small Chafer is also about the same length, and is numerous in some districts.

Lime and soot hoed into the ground, Vaporite, and similar preparations are all useful for destroying the larvæ. In small plantations many of the adult beetles may be secured by shaking them off the canes on to tarred boards. This, however, is one of the cases in which a remedy may be adopted where fruit is grown on a small scale, which is hardly practicable where several acres are concerned.

Other raspberry pests are:

LEPIDOPTERA: Garden Swift Moth, Dot Moth.
COLEOPTERA: Raspberry Weevil, Red-legged Weevil, Ground Beetle.
HYMENOPTERA: Raspberry Emphytus or Snag Borer.
DIPTERA: Cane Gall-fly.
HEMIPTERA: Raspberry Aphis.

Loganberry. Most of the enemies of raspberries also attack loganberries.

GOOSEBERRY PESTS

Gooseberry Saw-fly. The larvæ of the Gooseberry Saw-fly are generally the culprits responsible for the number of defoliated gooseberry bushes [60] so often seen in gardens and plantations. There are as many as three broods of these hungry grubs during the summer. The first hatch out from eggs laid by the adults which appear in April or May. The females lay their eggs under the leaves,

59. FIELD BREEDING-CAGE FOR INSECT PESTS

usually along the ribs, depositing them one by one in little slits made by saw-like instruments, which give them their name. In the case of these saw-flies, the slit is very slight, and the egg is not buried in the leaf, as is the case with the eggs of others of this class. The larvæ are green, with black heads and black spots, the last two segments being yellow. When fully grown, their colour will

be found to have changed to green of different shades and the spots disappear. They are about two-thirds of an inch long when fully grown.

Saw-fly larvæ can always be distinguished by the number of legs which they possess—three pairs of true legs in front, and seven pairs of prolegs; that is, abdominal legs, the larvæ of moths having only five pairs of prolegs.

By June or thereabouts the larvæ which hatched out first begin to pupate in a dull case of silk, the majority of them in the ground, though some have been found on leaves near the surface of the ground, but not in it. The cocoons vary from almost yellow to deep brown; the pupæ are greenish-yellow.

In about ten days or a fortnight the saw-flies emerge and lay the eggs for a second brood, and these run their course, and a third batch follows. The larvæ of this last brood spend the winter in the ground, pupating in the early spring, and changing to the first adults of the year, which were mentioned as appearing in April or May.

The Gooseberry Saw-fly larvæ being very ravenous feeders, they can make great havoc among the bushes; and a vigorous effort should be made thoroughly to rid the plantation of them.

Spraying with hellebore powder wash as soon as ever the early larvæ appear is beneficial. Where gooseberries are grown only on a small scale, it is a very good plan to look over the bushes every week or ten days, from the beginning of April, and carefully to pick off the leaves where eggs are found on them. A thick coating of lime and soot on the ground, to kill the larvæ when they fall to the ground preparatory to pupating, is also of use.

Other insects which attack the gooseberry are:

LEPIDOPTERA: Magpie Moth, Currant Clear-wing, Winter Moth.

HEMIPTERA: Aphis.

MOLLUSCA: Grey Slug.

ACARINA: Red Spider.

60. GOOSEBERRY BUSH DEFOLIATED BY THE LARVÆ OF THE GOOSEBERRY SAW-FLY

American Gooseberry Mildew. In these days, when there are so many prosecutions for sending to market gooseberries tainted with mildew, gooseberry mildew must not be passed over. It is a highly destructive fungous disease which has been brought over from America, but there is a European form, which is, however, not so virulent. The grower who discovers this disease on his bushes must at once, by Act of Parliament, notify the Board of Agriculture or local authority. A thin, white mildew appears on the tips of the young shoots, generally extending backwards for a few inches only [see page 1414].

The disease appears first on the fruit during the latter part of May or early in June, in glistening spots. The appearance of the mildew soon changes, and becomes powdery, which is due to the development of the light summer spores. These spores are carried by wind and other agencies to neighbouring bushes, which thus become infected. After a time it turns to brown, and covers both shoots and berries with quite a thick mould, which can be peeled off. Towards autumn, black spots appear on this mould. These are the winter fruit of this fungus, and contain the winter spores, which germinate the following spring, and give rise once more to the thin summer mildew.

Up to the present, although much research work has been done in connection with this disease, no real cure has been found for it. There are, however, certain precautionary measures ordered by the Board of Agriculture, who have the power to enforce their regulations. All infected bushes must be tipped; that is, the branches must all be pruned back for some inches, and the prunings burnt at once. This should be done in August or early September. As a precautionary measure, spraying in May and June will be found beneficial, and is advised by the Board. The best sprays are lime and sulphur wash and Bordeaux mixture. All berries showing mould should be picked at once and burnt.

European Mildew. This is similar, but much less virulent, and very seldom attacks the fruit itself.

RED CURRANT FOES

The Currant Clear-wing. This moth does damage to black and white as well as red currants. The moth has a body half an inch long, while the wing expanse is rather less; its body is of a bluish metallic colour with yellow stripes, and ends in a fan-shaped mass of purplish-black scales; the wings are transparent, with black edges tinged with orange. The moth may be seen on the wing in June in the early hours of warm days, but later in the day it rests often on the stems of currant bushes.

The female lays her eggs on the stems, usually one on a stem near a bud. They are oval in shape, and yellowish-white in colour. A tiny white larva with a brown head soon hatches out, and begins boring into the young shoots. From this habit it is sometimes called a "currant-borer." On reaching the pith, it works its way upwards and downwards, and the shoot flags and dies. The dying off of the shoots in the summer is very often an indication of the presence of these grubs. They pupate about April, and force their way partly out of the holes the larvæ made on entering, and emerge as the moth again in early June.

In winter, little holes about one-eighth of an inch across may be detected on the shoots. There is generally a quantity of frass around the hole. These shoots should be cut back till the end of the tunnel is reached. This is all that is at present known as a check to this pest.

Other pests attacking the red currant are:

LEPIDOPTERA: Currant-fruit Moth, Winter Moth.

HYMENOPTERA: Currant and Gooseberry Saw-fly.

COLEOPTERA: Glaucous-leaf Weevil.

HEMIPTERA: Currant Scale Aphis.

BLACK CURRANT PESTS

Black Currant Gall-mite. This, known as Big Bud, is by far the most serious pest of the black currant, and is of equal importance with the

American gooseberry mildew. It was in 1896 that it was first observed to do any extensive damage; since then it has spread rapidly.

The indications of this Big Bud are the dry, brown buds, which crumble into dust when pressed, and the large-sized, swollen leaf-buds, which are caused by very minute insects, called mites, which live within the bud. They are too small to be seen by the ordinary observer with the naked eye, being only

in May, which is the period of greatest migration, though they have been noticed migrating every month except January.

The other enemies of the black currant are the same as those which attack the red currant.

SPRAYING

Many fruit-growers consider spraying useless, and hold this opinion even after they have tried it.

61. KNAPSACK SPRAYER

62. NARROW-GAUGE SPRAYER

63. DRY-POWDER SPRAYER

From photographs supplied by courtesy of the Four Oaks Spraying Machine Co.

one-hundredth of an inch long, but when placed under a lens they will be seen to have two pairs of legs in front, a ringed body with five pairs of bristles, a blunt, snout-like head, and a kind of sucker at the tail end.

When a diseased bud is opened, the mites hold on to the plant by this sucker, and wave their bodies and legs about in the air, and are able to catch hold of passing insects, such as spiders and flies. It has

This attitude is usually bred by failure, due to some error in the manner of spraying, or a similar cause.

Some insects work only on the under side of the leaves. It is obvious, therefore, that if the spray is to be effective it must be applied to the under side of the leaves. Other insects lurk within the cracks of the rough bark; in this case a spray with a good force behind it must be used if it is to penetrate to the hiding-place of the enemy. Sprays such as

64. AMERICAN PETROL-SPRAYER

65. SPRAYER FOR WORKING FROM HEADLANDS

From photographs supplied by courtesy of Mr. Matthew Herrod, Wisbech

been found that in this manner, with the aid of other insects, they accomplish journeys far beyond their own power. An infested bud sometimes opens, but very rarely gives fruit of any use.

Winter spraying with lime, sulphur, and salt, also hand-picking infested buds, has been found beneficial, but the best results have been obtained by spraying the bushes twice a week for six weeks with sulphur and soft-soap. This should be begun early

Bordeaux mixture must be applied in the form of a mist, lest they should do damage by scorching. Lime, sulphur, and salt, and winter spray, however, will of necessity need a coarse spray, because of the thickness of the liquid which has to pass.

Spraying Machines. The type of spraying machine used varies necessarily with the size of the plantation or orchard, and the way in which it is planted. A young plantation, for

instance, planted with top trees and young bushes with rows of strawberries between, is not a suitable place in which to use a horse-drawn machine, as the horse would damage the strawberry plants. Nor, although the strawberries have been taken up, could a horse be used in the same plantation with the trees and bushes grown so that their branches nearly touch, as the branches would be liable to injury.

There are a large number of spraying machines on the market, individual firms making many different varieties. The uninitiated might, therefore, be confused, and, after seeing many, might very easily choose one that would turn out to be of little use for his purpose. For instance, one of iron or tin would be useless, as the first time Bordeaux mixture was used the sulphate of copper would eat into the metal.

Knapsack Sprayers. Starting with the smallest, the knapsack pattern must be mentioned as the most suitable for use in gardens, or where in a plantation a few bushes only require treatment. It derives its name from the fact that it is used strapped on a man's back, like a knapsack. One of the best of this form of machine is that known as the "World's Cheapest" [61].

Some of the more important points of this machine are: (1) Its light weight, compared with its capacity and quality. It weighs only 14 lb., although it is made of superior quality copper several gauges stronger than most machines of this class, and its capacity is 3¼ gallons. (2) It has a large-size internal air chamber with watertight lid. (3) The spraying rod is fitted with a strainer which prevents the nozzle getting clogged. There is also a strainer through which the liquid passes when filling the machine. (4) It has a double-swivel nozzle convertible into a single. (5) All parts are interchangeable and replacements are easily effected. (6) It has been specially constructed for lime, sulphur, and salt washes.

The next in size to notice is the Herrod's Narrow Gauge [62]. This machine is made in two sizes, the large size holding 18 gallons and the small size 10 gallons. As will be seen from the illustration, it consists of a narrow tank to which is fitted a pump with two lengths of hose.

It has been pointed out that a spray, to be effectual, must be put on with a good pressure. In the case of most hand pumps there is no pressure gauge to guide the worker, who, when he has been working some time and is tired, may fancy that he is spraying with considerably more pressure than he really is; or the pump may be out of order, causing the operator to work harder and giving him the impression that the pressure is higher than it really is. On this particular pump there is a pressure gauge on the air chamber in front of the operator as he pumps, so that he can see all the time what the pressure really is. It should never drop below 80. As the sprayer only has one wheel, and its extreme width is only 12 inches, it can be used either in a young plantation where strawberries are planted between the bushes, the wheel going between the rows of strawberries, or in an older plantation where the bushes have grown close together.

There are cases when it would be hard work for a man to push a pump of this nature filled with 18 gallons of spraying wash over the ground, as, for instance, where the ground is wet and water is standing about, or when a plantation has been freshly dug. There is a pump specially adapted for such circumstances. It is known as Herrod's Demon Sprayer [65], and is operated from the headland—that is, one end of the plantation—and only the hose itself has to be taken up among the bushes. The capacity of this pump allows, if necessary, for two gallons of wash per minute to be delivered at high pressure with only one man pumping. The illustration gives a good idea of its simplicity. The pump itself is constructed on scientific principles, ensuring the greatest efficiency and least possible loss by mechanical and water friction in working. There are two delivery hose-pipes on one side of the pump, while a suction hose, which is 8 ft. long, is attached to the opposite side for sucking the spraying wash out of a tank or barrel.

A Petrol Sprayer. None of the foregoing are suitable for large plantations; large areas require a power plant for economical working. One that has deservedly received a good deal of commendation, because of its simplicity, efficiency, and compactness, is Herrod's American Petrol Sprayer [64]. Moreover, it is cheaper than many of those on the market of a similar class. As will be seen from the illustration, it is mounted on a truck and can be pulled by hand.

Power Spraying. All the machines that have been mentioned are for the use of commercial preparations, but some fruit-growers may prefer to boil their own lime, sulphur, and salt wash, and the illustration [68] shows a plant in use on one of the fruit farms of Messrs. Chivers & Sons, the well-known jam manufacturers of Histon, which is an arrangement for boiling the washes, with a triple plunger pump attached for forcing the spraying mixtures out into the orchards and plantations. The engine supplies the steam for boiling the washes and the power for driving the pump and agitators.

Powder Sprays. The appliances mentioned so far are all for wet sprays, but, as has been stated, sometimes the spray is applied in the form of a powder, as, for instance, in the case of strawberry mildew.

There are several knapsack pattern pumps for this purpose, but here again the "Four Oaks" Spraying Machine Co. has placed one on the market that has many advantages over others. It is very light and very easy working. All the working parts are visible and easily accessible, and thus simple to dismount and clean. It is quickly filled; the powder can be emptied straight into the container from the bag, no scoop being required as for the other makes, thus saving time. It also has a vaporiser jet—as far as can be learned, the only jet of its kind on the market—which distributes the powder in a very even way, and permits the flow of powder to be instantly regulated at any time. It is also the only machine that can be filled with powder, and holds twice as much as any other machine of the same size, its capacity being 18 lb. [63]. This sprayer is, naturally, only suitable for gardens or small strawberry fields.

Mr. Herrod, of Wisbech, has brought out a horse-drawn powder sprayer [69] that is eminently suitable for both strawberries and potatoes. As will be noticed from the illustration, the wheels are very high (5 ft.), with a ratchet attached, and so constructed that they are interchangeable. The hopper is large enough to hold powder sufficient for several acres. The powder is distributed by means of a fan, and is brought to the fan on two endless chains, one on either side of the hopper, thus ensuring a constant, regular, and even supply. The quantity of powder

66. SPRAYING FRUIT-TREES IN THE WINTER

67. A GENERAL VIEW OF SPRAYING OPERATIONS ON A LARGE PLANTATION

From photographs by courtesy of Messrs. Chivers & Sons, fruit-growers, Histon

blown out can be regulated from 20 to 40 lb. per acre. It is a light load for a horse, and only requires one man to work it. The powder is forced by the fan through five direct deliveries, armoured hose conducting the powder from the machine to steel tubes, which can be raised by the driver to any angle by means of a lever. At the extreme end of the steel tubing spreaders are fixed in a manner that ensures the fungicide being distributed to the under surface of the strawberry leaves or potato haulm.

Formulæ for Fungicides. The following are some of the more important fungicides:

Bordeaux Mixture. One of the best fungicides is Bordeaux mixture. The best time for spraying apple-trees for the scab is directly after the blossoms have fallen. The mixture should always be freshly made, with the following ingredients: Sulphate of copper, 4 lb.; freshly burnt quicklime, 4 lb.; soft water, 50 gallons.

Care should be taken to dissolve the sulphate of copper in about 4 gallons of water in a wooden tub; never use an iron or tin receptacle. Place the copper in a piece of sacking, and leave in the water overnight. Slake the lime in another tub, adding only a little water at a time until it is like milk; then add the rest of the water. After it has been well stirred, allow it to remain a little

68. SMALL POWER SPRAYING PLANT

while, so that it will settle; then pour off the liquid and add the solution of sulphate of copper. Finally, carefully strain. In applying it to the trees, use a very fine nozzle.

Bordeaux mixture and arsenate of lead make a very useful combined spray—that is, one that is an insecticide as well as a fungicide. The arsenate of lead is used for leaf-eating caterpillars. The Bordeaux mixture is made as already described, with the exception that only 25 gallons of water are used. To this is added 2 to 3 lb. of arsenate of lead paste that has previously been mixed with 25 gallons of water.

Liver of Sulphur. This is used for mildews, such as the summer stage of the American gooseberry mildew. The formula is: Liver of sulphur, 1 lb.; water, 32 gallons.

Nicotine. This makes a very useful wash against aphis and apple-sucker. Formula: Nicotine (95 per cent. pure), 1 lb.; water, 130 gallons.

This wash should be used just before the trees come into bloom, or while they are in blossom, as nicotine does not hurt the blossoms.

Lime, Sulphur, and Salt Wash. The formula (winter strength) is: Lime, 44 lb.; sulphur 22 lb.; salt, 12 lb.; water, 80 gallons.

The sulphur should be placed in a tub to soak for about an hour before it is required. The lime should be placed in a tank in which it can be boiled, and made into a cream by adding water. When this is made, the sulphur that has been soaking should be added, and the balance of the water, making it up to 80 gallons. It should then be brought to a boil and boiled for one hour. About ten minutes before it is finished boiling the salt should be added. The wash should then have a deep amber colour, but if it is green in appearance it has been over-boiled.

Paraffin Emulsion Wash. The formula for this wash, for use in the winter only, is: Paraffin, 8 gallons; soft-soap, 12 lb.; water, 80 gallons.

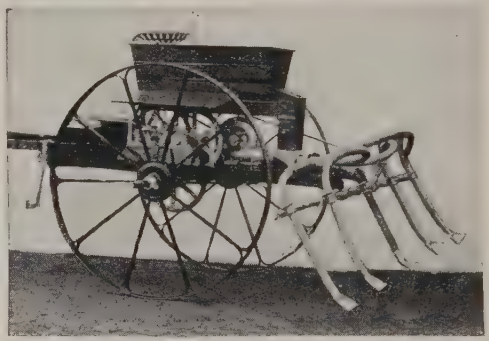
For use in the summer, the formula is: Paraffin, 4 gallons; soft-soap, 12 lb.; water, 80 gallons.

Dissolve the soap in boiling water, and, while still on the boil, add the paraffin; then thoroughly churn into a creamy liquid. These paraffin emulsion washes are used against aphis, and so on. Either Tea Rose or White Rose oils will do.

Hellebore Powder Wash. The formula is: Freshly ground hellebore powder, 2 lb.; water, 10 gallons.

Simply mix the two together, taking care that this is thoroughly done. This wash is used against all saw-fly caterpillars.

Sulphur and Soft Soap Wash. The formula



69. HERROD'S POTATO AND STRAWBERRY SPRAYER

is: Flowers of sulphur, 2 lb.; soft-soap, 25 lb.; water, 50 gallons.

Black currant bushes should be sprayed twice a week for six weeks, beginning early in May for the big bud or black currant gall mite.

Lime and Sulphur Wash. The formula for this wash is: Flowers of sulphur, 2 lb.; quicklime, 2 lb.; water, 50 gallons.

Black Currant Wash. A combination wash for black currants, when they are attacked with the black currant gall mite and winter moth, consists of: Soft-soap, 22 lb.; sulphur, 5 lb; lime, 2½ lb.; arsenate of lead, 2 lb. Boil for 1 hour.

Paraffin, Soft Soap, and Lime Wash. This wash, which is for use against woolly aphis, consists of: Paraffin, 10 lb.; soft-soap, 4 lb.; lime, 2½ lb.; water, 80 gallons.

Boil in soft water for thirty minutes. Apply to the trunks of the trees with a stiff brush, seeing that the fluid goes well into the cracks and crannies. Spray the upper part of the trees.

Carbon Bisulphide. Carbon bisulphide should be injected into the ground in ¼ oz. injections, the number varying according to the size of the trees, care being taken to see that the injections are made about two feet away from the trunks of the trees, and that the injector does not actually touch a large root.

The Principal Processes for Softening Water for Industrial Purposes. Treatment of Effluents and Waste Products from Factories and Chemical Works.

WATER SOFTENING & USE OF WASTE

Soft Waters for Domestic Use. In places where the water as ordinarily supplied is hard, and both wasteful and unpleasant to use, people would do well to remember that prevention is better than cure, and turn their attention to other and more suitable sources of supply. Why not use rain-water? A simple calculation will show that the water from the roof of a house, if caught and utilised, would be sufficient for a large proportion, and, in some cases, for the whole, of the requirements of the inhabitants. In most cases such water goes to waste.

Removal of Impurities. After a shower, the first water from the roof of a house carries with it a quantity of soot, black, birdlime, etc., which would spoil the colour of the rest, and give to it other undesirable qualities. By an ingenious contrivance, such as the Roberts Rain-water Separator [4 *A* and *B*], the dirty portion, consisting of the first washings from the roof, is automatically run to waste, and the rest, consisting of the clear and good water, is stored for domestic use. Such apparatus can be purchased for from £3 to £6. The saving to the household due to the absence of scale in kitchen boiler and kettle will quickly pay for the cost of installation. Moreover, such water is by many people much preferred for washing and for baths, and naturally the saving in soap alone amounts to something substantial per annum.

1. WASTE OF HEAT DUE TO SCALE IN BOILERS

For small villa houses and cottages a water-butt should be placed to catch the rain-water. A rum-puncheon of 100 to 120 gal. capacity should be used where possible, and even a 40-gal. cask is not to be despised.

Soft Water by Distillation. Soft water is prepared by distillation from sea-water. Extremely efficient appliances for this purpose render such water available for industrial and domestic purposes in seaside places where other water cannot be obtained at a reasonable cost. Of course, such apparatus is indispensable on board ship on long voyages. By such a process water is not only freed from its mineral constituents, but it is also rendered sterile.

Scale in Boilers from Hard Waters. But the chief purpose for which water is softened is for steam raising. Here, softening is not a matter of convenience, but of necessity, to ensure both safety and economy.

As Harold Collet stated: "The waste of fuel occasioned by scale and blowing out must be remembered when considering the cost of a water supply, from whatever source. The cost of the water before it enters the boiler is a mere nothing compared to the cost of evaporating it. Many waters would be dear at 1d. per 1000 gal.; others are cheap at 1s." Hard water wastes fuel according to the thickness of scale in the boiler. With a moderate thickness of scale the extra resistance to heating may be twenty times as great as that of the boiler shell itself. The diagram [1] shows graphically the waste of heat entailed. There is also risk of explosion owing to the unequal heating of the boiler shell.

Water-softening by Chemicals. The hardness of water may be described as of two kinds —*temporary* and *permanent*— the former so called because it can be removed by prolonged boiling.

Temporary hardness is due to the presence in the water of bicarbonates; that is to say, lime and magnesia combined in certain proportions with carbonic acid. Bicarbonate of lime is so called because it consists of two equivalents of carbonic acid and one equivalent of lime; it is soluble in water, and is contained in most natural waters. On the other hand, carbonate of lime—that is, one equivalent of carbonic acid combined with one equivalent of lime—is insoluble in water, and therefore, if formed, separates out from solution. If, therefore, the bicarbonates can be converted into carbonates, they will come out of solution as a deposit, which can be removed, and the temporary hardness so got rid of. It is obvious from the foregoing that the bicarbonates can be converted into carbonates by removing one equivalent of carbonic acid, and this can be done in two ways—either by boiling the water for some time, causing part of the carbonic acid gas to be driven off, by which the bicarbonates are converted into carbonates, or, secondly, by adding slaked lime—that is, pure hydrate of lime or calcium hydroxide—in the right quantity. One part of carbonic acid in the bicarbonate is taken up by this fresh lime, so that the soluble bicarbonates disappear with formation of insoluble carbonates.

Permanent hardness, like temporary hardness, is caused by the presence of certain salts in solution in the water, of which the more important are calcium sulphate (sulphate of lime), calcium chloride, magnesium sulphate, and magnesium chloride. All four compounds affect the test for hardness already mentioned. Calcium sulphate gives rise to the hardest scale, but can be removed by adding soda ash (carbonate of soda) to the water. What is known to chemists as "double decomposition" takes place. Sulphuric acid leaves the lime and combines with the soda, whereby are formed sulphate of soda, which does not form scale, and carbonate of lime, which is removed by subsidence or filtration. The insolubility of carbonate of lime is the prime factor in the change.

Water Softened by Heating. There are many forms of apparatus used for water-softening, all of which may be said to have been evolved from the same simple process first used by Dr. Clark, of Aberdeen, which merely consisted in adding clear lime-water to hard water containing bicarbonate of lime or magnesia in solution. This, by combining with one half of the carbonic acid, throws down a double precipitate of chalk. Prior to Clark's process, water was softened without any plant at all. Clark's process is expressed by the equation

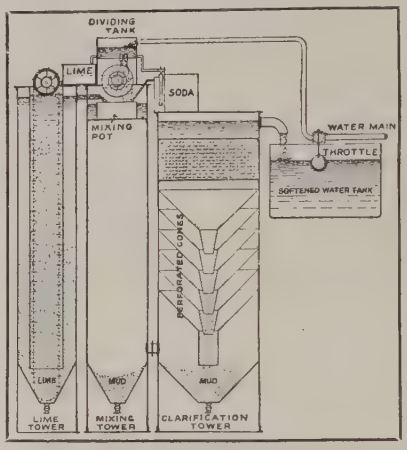
$$\underset{\text{Bicarbonate of lime (soluble)}}{CaH_2(CO_3)_2} + \underset{\text{Lime}}{Ca(OH)_2} = \underset{\text{Chalk (insoluble)}}{2CaCO_3} + 2H_2O$$

The softening of water by heating is expressed by the simple equation

$$\underset{\text{Bicarbonate of lime (soluble)}}{CaH_2(CO_3)_2} = \underset{\text{Chalk (insoluble)}}{CaCO_3} + \underset{\text{Carbon dioxide}}{CO_2} + H_2O$$

Upon this principle one of two well-known processes are based, notably on the Continent. Thus we have Scham's apparatus, in which water is forced into a dome, passing as a fine rain through perforated grids, mounted so that the holes do not come vertically over one another, the waste steam from the boiler passing between and heating the water sufficiently on its way downward to cause it to deposit its lime salts before it passes into the boiler. We have also Howatson's softener, a cylindrical reservoir containing plates arranged in stages in a manner so that the water travels in a zigzag fashion until it reaches the bottom, when it is softened, a ball-cock at the bottom regulating the inflow at the top. For further information regarding such processes, see "Industrial Use of Water," by H. de la Coux (Scott, Greenwood & Co.).

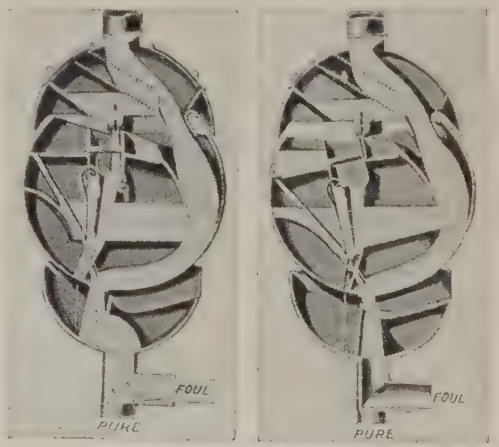
3. STANHOPE CLARIFYING TOWER (Stanhope Engineering Co., Ltd.)



2. DIAGRAM OF STANHOPE WATER SOFTENER
Stanhope Water Engineering Co., Ltd.

The Stanhope Softener. In the Stanhope Water Softening Process [2 and 3] we have illustrated an effective means of removing the sediment by gravitation. The water from the main, which is automatically controlled by means of the throttle, enters the top tank just in proportion as it is removed from the softened-water tank. In its flow through the driving tank and the mixing-pot it drives a water-wheel, which in turn drives a mechanical stirring apparatus for the lime-water. A continuous stream of clear saturated lime-water passes to the mixing-pot, together with the water to be softened and the soda in proportion required. It then passes down the mixing tower, where some sediment is deposited, and up the clarifying tower [3], where the rest of the deposit is caught by settlement on the cones, and drops to the bottom through the spouts. The softened and clarified water emerges from the top. The process is entirely automatic; and as long as the apparatus is charged, and periodically blown off, it can be kept going indefinitely.

The Collet-Stanhope Water Softener is somewhat different from the foregoing, as shown in 5.



4. ROBERTS RAIN-WATER SEPARATOR
A. shows impure water passing to waste;
B. shows pure water passing to storage.

The Criton Softener. In the Criton Water Softener [7, page 3431], made by the Pulsometer Engineering Company, accurately measured quantities of hard water, lime-water, and soda solution are discharged together into the mixer at every discharge of a large siphon tank. The capacities of the two reagent measures can be easily and rapidly varied when required. The discharge of the reagents is exactly dependent on the quantity of water to be softened. If this is reduced, the siphon tank fills fewer times per hour, and consequently the number of times the reagent measures discharge is reduced in proportion.

The discharges from the hard-water siphon tank and from the lime and soda tanks all meet at the same time and at the same place—namely, the mixer—and are violently dashed together, thus ensuring an immediate and thorough mixture. From the mixer the treated water passes through a down pipe to the bottom of the settling tanks, whence it steadily flows upwards, depositing in its progress the heaviest of the suspended matter, caused by the action of the softening process. From here it passes through the filter, emerging at "filter outlet" soft and bright. The filter is cleaned, without the removal of the filtering medium, merely by opening and closing certain valves. The lime tank is recharged with lime daily, and the spent lime drawn off.

Permutit. This substance, which marks a departure in the softening of water, is an artificial zeolite of approximately the following composition:

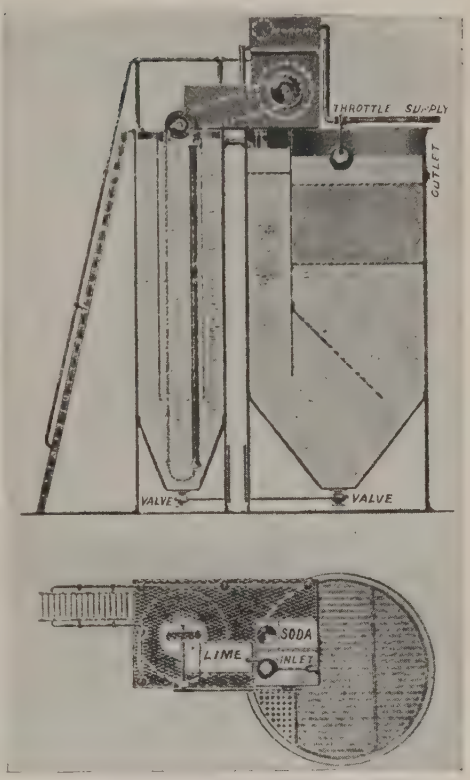
$$2SiO_2Al_2O_3Na_2O.6H_2O.$$

On passage of water to be softened through a mass of this sodium permutit, as it is called, it becomes converted into the calcium or magnesium salts, and the lime and magnesia salts in the water become converted into the corresponding soda salts, which, of course, are devoid of hardness.

As sodium permutit, the condition in which it is used, it is of a moist nature, granular and flaky, and possesses a lustre like that of mother-of-pearl. This constitutes the active agent in softening the water. When the whole of the mass is converted into calcium permutit, it has merely to be revivified by treatment with a solution of brine, which turns it back into the sodium salt for use over again. The final waste product is calcium chloride. Two illustrations show the appliances used by Water Softeners, Ltd., both for use by the gravity and pressure systems [6].

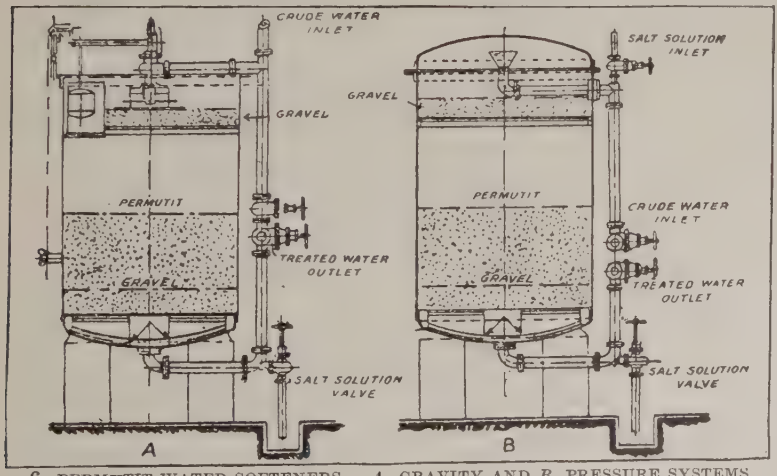
The softener consists of a cylindrical tank, either of the open (gravity) or closed (pressure) type, containing filters of gravel and permutit, with suitable arrangement of pipes and valves for washing and regenerating, together with a small tank for the salt solution.

The water enters through the crude water inlet-pipe, and, passing through permutit, is deprived of all the calcium and magnesium salts (which combine with the permutit). It is then delivered at the treated water outlet, clear, absolutely soft, and free from all hardening salts.



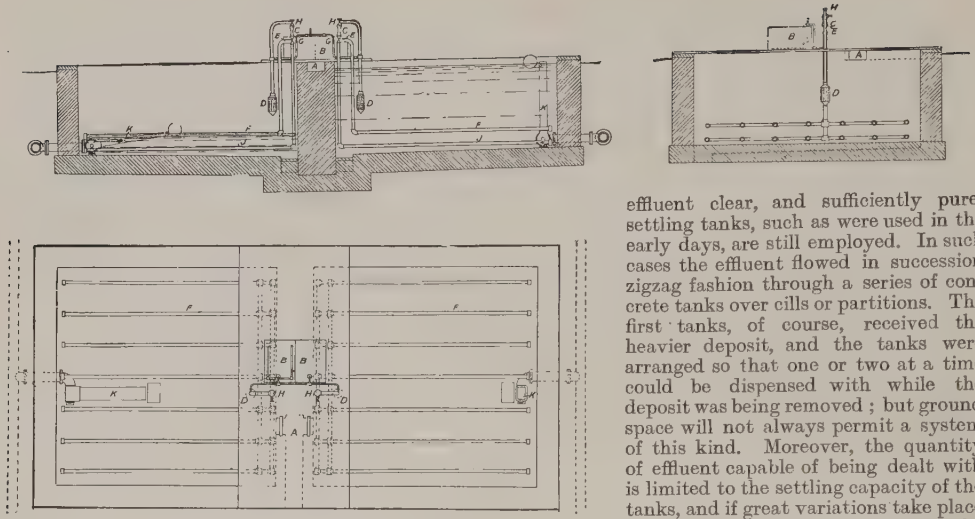
5. COLLET-STANHOPE WATER SOFTENER
(Stanhope Engineering Co. Ltd.)

The cleansing of the permutit is carried out by merely reversing the flow of the water through the filter. For regeneration a 10 per cent. salt solution, contained in a tank placed above the filter, is allowed to run slowly through the permutit after cleansing. This operation takes about eight hours, and requires no attention. The filter is afterwards washed with the hard water until free from salt, when it is again ready for use. These softeners can be built in single units of a capacity of from 10 to 10,000 gallons per hour, and in multiple units to any size



6. PERMUTIT WATER SOFTENERS. *A*. GRAVITY AND *B*. PRESSURE SYSTEMS

Settling Accelerated by Agitating. In Clark's process the precipitate is allowed merely to settle in large concrete or iron tanks, and the clear water is drawn off from the top. The precipitation is comparatively slow; but if the deposit at the bottom is stirred up each time, the settlement of fresh deposits is much accelerated, on account of the heavier crystals entangling and carrying down the lighter ones. This principle is carried out in a scientific way in plant constructed by



7. PATENT EFFLUENT WATER PURIFIER
(Mather & Platt, Ltd., Manchester)

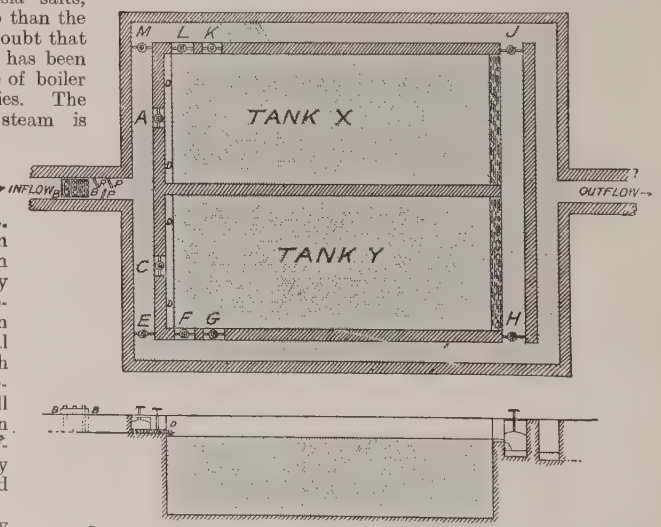
Messrs. Mather & Platt, of Manchester [7], which can be understood by reference to the figures: A, Effluent water inlet; B, tank for dissolving chemicals; C, blower for air and mixing chemicals; D, perforated rose; G, three-way tap; H, air tap on blower; F and J, perforated pipes for air; K, floating discharge pipe. The blower not only disturbs the sediment, but mixes the chemicals. A great saving in time of settling is established, and consequently a greater output of softened water is obtained. Furthermore, the plant is suitable not only for ordinary softening, but for purification. Some waters which are not amenable to carbonate of soda and lime treatment alone can be treated by the use of these chemicals in conjunction with alum. Water so softened is also rendered organically purer, as careful trials have proved.

The Removal of Grease from Water. The removal of lime and magnesia salts, although important, is not more so than the removal of grease, as there is no doubt that the presence of grease in feed water has been frequently the cause of the collapse of boiler tubes and other serious casualties. The removal of grease from exhaust steam is effected by oil separators, such as Baker's [9], of which there are many sizes and patterns to meet the various requirements.

Treatment of Effluents. The purification of effluents from different works has largely been forced upon the manufacturers by legislation, but of later years the products resulting from such purification have been found to be of industrial importance, and therefore in such cases, even if restrictions were removed, the manufacturers would still continue the processes of purification for their own advantage. An important case in point is the recovery of waste liquors from esparto and wood boiling [see Paper-making].

Where mere subsidence will carry down the particles and leave the effluent clear, and sufficiently pure, settling tanks, such as were used in the early days, are still employed. In such cases the effluent flowed in succession zigzag fashion through a series of concrete tanks over cills or partitions. The first tanks, of course, received the heavier deposit, and the tanks were arranged so that one or two at a time could be dispensed with while the deposit was being removed; but ground space will not always permit a system of this kind. Moreover, the quantity of effluent capable of being dealt with is limited to the settling capacity of the tanks, and if great variations take place in quality and quantity of effluent, the treatment is likely to be unsatisfactory. It must be admitted that the Rivers Commissioners are very reasonable in their requirements, and so long as manufacturers show that they are exercising their best endeavours to fulfil such requirements they are not unduly harassed; but upon the manufacturer is placed the onus of devising a scheme for the treatment of his effluent, and it necessitates a great deal of ingenuity on his part to choose between the many well-known processes so frequently brought to his notice.

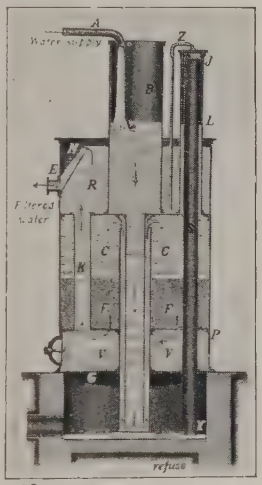
We have known cases where troublesome effluents have been treated at very small outlay by digging sumps where the ground is impermeable, and causing the water to flow over a succession of terraces like those arranged for watercress beds. Such primitive appliances at times do more to satisfy requirements than complex filters. Figure 8 shows an arrangement of settling tanks.



8. TANKS FOR PURIFICATION WITH ALUMINOFERRIC
(Peter Spence & Sons)

"Reisert" Automatic Self-cleaning Filter. This [10] is used for clarifying turbid or muddy water for industrial purposes. The water to be filtered is received into the chamber B, and flows downwards, following the course of the arrows into the chamber C, and so reaches the filter bed, F, through which it percolates, leaving the mud, etc., on the upper side of the bed. The filtered water is received into chamber V, and finds its way upwards *viâ* pipe K into chamber R, and finally overflows the diaphragm, N, into the filtered-water outlet, E. Obviously, the rate of filtration will vary with the state of the filter bed and the head of water in B. As the filter bed fouls and the resistance to the flow of the water increases, the water level in B rises and establishes a corresponding level in the pipe L, which, it will be observed, is in connection with C. Inside this annular pipe, L, is another pipe, S, which extends from nearly the top of L right through the filter bed and receiver V to the waste water channel G, forming the base of the filter. As the water rises in L, in sympathy with B, there presently arrives a time when it overflows at J, and so forms a syphon. The current through the filter is thus rapidly reversed, the water in R flowing back through K and upwards through the filter bed, the deposit on the filter being thoroughly disturbed and carried into the waste channel, G. The chamber R is proportioned to contain sufficient water to effect this cleansing operation thoroughly, and as this chamber empties, air enters and destroys the action of the syphon, and the cleansing ceases. The filter then resumes its normal working. The cleansing operation is repeated as often as the state of the filter requires, and is entirely automatic.

9. THE BAKER OIL SEPARATOR



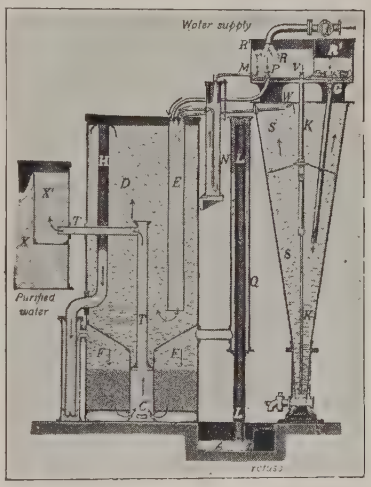
10. REISERT AUTOMATIC SELF-CLEANING FILTER (Royles, Ltd.)

The same system is used in conjunction with the water softener [11]. This latter is peculiar in its construction, and different from any of the foregoing. The lime saturator, S, is cone-shaped. The charge of slaked lime is inserted through tank R′ once daily.

By a constant uniform water supply from the distributing tank, R, which is conducted downwards through the central pipe, K, through micrometer valve V, the lime paste at the bottom is stirred up and thoroughly impregnated, so that it rises at first partly with the water, until the rapidity of the rising water diminishes so much, owing to the upward widening shape of the saturator, that the undissolved lime particles are no longer able to follow, so that the saturated lime-water clarified, then leaves the saturator, S, at the top, through the pipe W, and is carried away into the reaction chamber, D, by way of the mixing pipe, E. The soda apparatus is charged with strong soda solution once daily, and being much heavier than water, it remains at the bottom.

The water flowing from the distributing tank, R, through the small micrometer valve M—which is adjusted in accordance with the amount of soda required—into the soda chamber, N, remains always on the surface of the soda solution (no mixing occurs) and displaces the same, it being carried through the small pipe from the bottom upwards, and into the mixing pipe, E, and finally into the reaction chamber, D. The softening takes place in D, and the water, after softening, passes down through the filter, F, up into the tank X′, where it overflows into the tank. N is the syphon for flushing the filter. In all respects it acts in a similar way to the cleansing filter already described [10].

The "Torrent" Filter. This represents a type with which we have not dealt. It is extremely simple, and costs very little for upkeep.



11. REISERT AUTOMATIC SOFTENER (Royles, Ltd.)

The great feature of this filter is that the filtering medium is cleansed and revivified by introducing for a few minutes, at intervals of about ten hours, a jet of air under high pressure produced by the aid of a steam blower, and at the same time admitting a reverse current of water. The violent agitation so produced causes the whole of the filtering medium and contained impurities to boil up, as seen in **12.** The particles of dirt are washed away and discharged through the outlet, leaving the filtering medium clean. The medium never requires to be replaced by fresh, and what little there is lost through the dirt is easily made up by the addition from time to time of small quantities. The filtering medium is chosen to suit the requirements of the particular water which is to be treated. There are no mechanical moving parts to get out of order.

Filtration. For laboratory work special filters are constructed, the simplest, perhaps, being the Kitasatos porous tubes in addition to which we have the Chamberland porous filter [14], which can be mounted in metal tube with stopcock to fit

a water supply. There are also the Massen filter candles with porcelain heads [15], and the well-known Klein laboratory filter, fitted with Pasteur-Chamberland filter tube [13].

For domestic work we have very much the same kind of contrivance working under pressure. In some of them dirt is quickly removed by the reversal of the current of water. Numerous other filters and water softeners, both for domestic and manufacturing purposes, have been invented, and are in use, but it has been possible to consider only some of the typical processes here. One of the most simple and effective for the clarification of an ordinary mill effluent is that recommended by Peter Spence, to be employed in conjunction with aluminoferric, which is now so much used for the purpose.

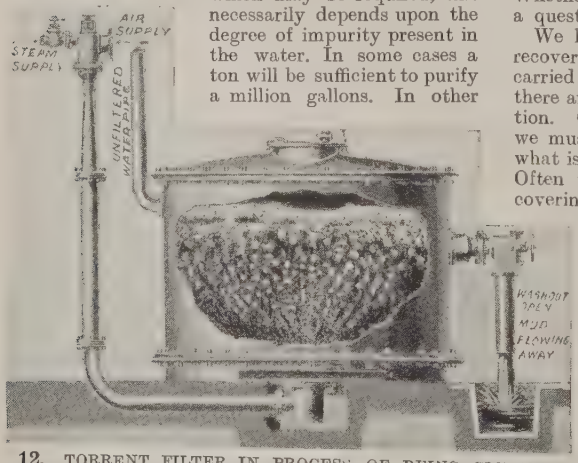
How to Apply Aluminoferric. Figure 8 gives a general idea of the method of using aluminoferric, also of a system of settling tanks which, we think, may with advantage be adopted by many manufacturers for purifying their waste water. BB represents the box or cage containing the aluminoferric standing in the channel or conduit. PP represents a series of baffle plates to insure the aluminoferric being thoroughly mixed before flowing into the tanks. The two tanks shown may be used in two different ways as may best suit the special circumstances of each manufacturer.

13. KLEIN'S LABORATORY FILTER

They may be used independently by opening A and C and closing E and M. The treated water will thus pass into both tanks, where precipitation will take place, and, when full, will flow over the sill at the end, and, H and J being open, the clarified water will pass away into the outfall.

Alternately, C and E and M being closed, the treated water will flow into tank X, and passing forward will overflow into the channel at the end, and H and J being also closed, the water will flow into tank Y, and F and G being open, will flow into the side channel and pass away into the outflow as in the first instance. Or the working as described may be reversed by closing A and M and opening K and L.

With regard to the quantity of aluminoferric which may be required, this necessarily depends upon the degree of impurity present in the water. In some cases a ton will be sufficient to purify a million gallons. In other instances, where the water is highly impure, experience shows that it may be necessary to use a quantity equal to two tons per million gallons.



12. TORRENT FILTER IN PROCESS OF BEING CLEANED
(Pulsometer Engineering Co., Ltd.)

The price of the aluminoferric may be taken at £2 15s. per ton, in four-ton lots, delivered at railway station within, say, 50 miles of Manchester or Goole. The superior results obtained by this process have enabled manufacturers in many instances to utilise the clarified water for manufacturing purposes, and where this has been done, it has been found that the purification is accomplished practically without expense.

Recovery of Fibres. Objections are raised to effluents from mills containing fibrous particles, which may be harmless in themselves but will spoil the appearance of the stream. They are frequently collected for economic reasons and used again in the manufacture.

Perhaps the simplest appliance for catching fibres from effluent is an ordinary "save-all," which consists of a revolving cylinder slightly tapering and revolving slowly on a horizontal axis and covered with fine wire gauze. The water passes in at the small end and drains through, the fibre is caught and discharged at the other end of the drum. The well-known Fullner Separator, which takes the fibres out by a process of settlement, has now become a part of the general equipment of a mill. After this clarification process, the fibre collected is used again in the manufacture.

We do not profess to deal with the subject of sewage purification [see page 3686], but there is no hard and fast line dividing such purification from that of mill effluents, because the latter includes many cases which require to be submitted to similar treatment to sewage, as, in addition to removing chemical impurities, it becomes frequently necessary to destroy organic contamination. We have, therefore, practically all the methods of sewage purification employed in conjunction with existing works on effluents, even to the bacterial process.

Can Waste Products be Utilised? There are many so-called waste products which are now turned to useful account, and therefore no longer regarded as such. In fact, as we all know, there should be no such thing as a waste product. Whether or not it can be utilised becomes merely a question of cost.

We have to inquire under what conditions the recovery process and utilisation of waste can be carried out economically. To answer this question there are several factors to be taken into consideration. Quite apart from the nature of the products we must know the quantity to be treated, and, what is even more important, the state of dilution. Often the quantity is insufficient to pay for recovering, even although excellent processes may be elsewhere in operation. If waste liquors are to be treated they must not be too dilute; thus it pays to recover the alkali from esparto liquors but not from rag liquors, as the latter are usually too dilute and the cost of evaporation would be too great. It might, however, pay where esparto and rag liquors are treated together.

As another illustration, we recently examined a quantity of waste fibrous material with a view to utilising it or finding a suitable outlet. We found that the material yielded, on dry distillation,

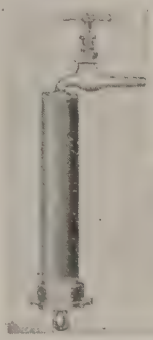
a high percentage of acetic acid and wood spirit; but although some hundred tons were available per annum, the quantity was too small for a plant to be constructed to work it economically. In such a case the only alternative is to look around for similar waste products which could be treated in the same plant.

Slag and Mineral Refuse. Considerations such as we have outlined above apply to practically all waste products. Take, for instance, the case of blast furnace slag. Enormous quantities of this material have been accumulating, and may be seen as huge mounds or heaps by the side of the furnaces. Numerous projects have been put in hand for utilising this waste, but consider some of the initial difficulties. In many parts furnaces are scattered up and down the country in twos or threes, and to utilise the slag economically it must be worked up on the spot. We will suppose plant and machinery is installed, what is to happen when that particular heap of slag is exhausted, and it costs too much to bring it from a distance? Nevertheless, slag is being employed for a number of purposes. In many parts it is used as a road metal, although not very suitable for this purpose. It is also used for making bricks, paving slabs, wall copings, ornamental blocks, etc., with the addition of lime and cement as bonding agents. Other waste materials, such as slate refuse, clinkers from destructors, stone chippings, and even sand may be similarly treated. These materials are first fed into a heavy revolving grinding mill, and reduced to fine powder by passing through screens and returning the coarse stuff to be reground, as described in the manufacture of ordinary bricks [see page 1799]. The resulting ground material is then measured out with the "bond," whether lime or cement, in the correct proportions, and delivered into a mixer under a spray of water, and thence the material passes to the mixing pan—a machine similar to, but lighter than, the grinding mill, and, when reduced to the correct consistency, it is conveyed to the brick-making machine. The moulded bricks are dried either in the usual manner by air hardening or by a more rapid process. By heating the bricks in an autoclave [16] under 120 lb. steam pressure, they can be hardened and ready for the market in 24 hours.

Blast furnace slag and Portland cement resemble one another in composition, and successful attempts have been made to prepare cement from this material, but in spite of all inventions there is plenty of slag left for the chemist to work upon.

Other Examples. Numerous examples of the utilisation of waste products will be found in studying any industrial process. Thus, the glue-maker depends on the waste pieces of hide or leather clippings and the waste bones from the slaughter-house or dust heap [see page 5067]. The manufacturer of animal black uses waste animal refuse of all sorts. The farmer feeds his stock on cotton-seed or linseed cake, from which the valuable oil has been extracted [see Cattle Foods], on bran and pollard from the flour-mill [see page 5272], on brewers' grains [see Brewing], and numerous other so-called "waste products," of which not an ounce is really wasted.

Sometimes the waste is employed again in the same factory in which it was originally produced, as in the case of metals melted down for use again, or in the "regeneration" of waste rubber. Perhaps coal-tar is the most striking instance of what was once but can no longer be regarded as waste [see page 5197].



14. CHAMBERLAND POROUS FILTER

15. MASSEN'S FILTER CANDLE

One of the most troublesome sources of contamination to streams is the effluent from flannel mills which is derived from the processes used in washing wool. Wool always contains a proportion of fatty substances, the greater part of which, however, resemble fat only in appearance, and not in chemical properties. These consist of a body termed *cholesterine*, belonging to the class of substances known to chemists as *alcohols*. Chemically, wool fat is more difficult to decompose than ordinary fats, and, in consequence, hangs about and contaminates any water or stream into which it finds its way. As potash is used in wool-washing, it pays to evaporate the waste liquors instead of allowing them to become an effluent, and, after concentration, to ignite them, when the potassium is recovered in the form of potassium carbonate. The ash is lixiviated, and the liquor used over again for wool-washing.

One of the waste products for which no really satisfactory use has been found consists of the sulphite liquors remaining over after the preparation of wood pulp [see Paper-making]. These liquors have been worked up for the separation of sizing materials, but without much commercial success. The latest attempts lie in the direction of the production of cattle foods, but reliable data are not yet to hand.

Perhaps one of the most difficult of all problems is the utilisation of town refuse. A large proportion of the solid matter is of a nitrogenous nature, and were it in the same suitable condition as it is sometimes found in country districts, it would prove a most valuable manure. Unfortunately, in large towns and cities it becomes diluted with such large volumes of water that the economical separation of the more valuable constituents becomes one of the most difficult problems with which we are faced. On the other hand, we cannot but view with concern the large quantities of combined nitrogen which are constantly being removed from the soil and deposited in the sea. The solid matter of town refuse is now frequently burnt, combustion taking place in special furnaces or destructors. In many towns the heat so produced is utilised for steam-raising.

Signalling Systems and their Methods of Working. Railway Brakes. Vacuum and Westinghouse Systems.

RAILWAY SIGNALS AND BRAKES

BRITISH railways are worked on the absolute block system, the object of which is to maintain a certain interval of space between all trains, instead of an uncertain interval of time as formerly. The line is divided into sections, varying in length from a few chains to several miles, according to the volume of traffic. A signal-box is placed at the termination of each section, and provided with a number of fixed signals outside, and within are the levers that actuate the movements of the signals and points, together with electric bells, block telegraph instruments, and telephones. The principle of the block system is that two trains travelling on the same set of rails shall never be in the same section at the same time, though this rule is relaxed in certain circumstances by employing what is known as the *permissive block* system, which is governed by stringent conditions.

Semaphores. The form of fixed outdoor signal generally adopted is the *semaphore*, which consists of a timber or iron pole, varying in dimensions according to circumstances, but usually from 20 ft. to 30 ft. high, with an arm about 5 ft. long, capable of assuming two positions when actuated by mechanical force. When this arm is in its normal position—namely, horizontal and at right angles to the post—it signifies "stop"; when it is turned at an angle of 45 deg. downwards it indicates "go on." Of all semaphore signals none has a less equivocal "go on" or safety position than the Great Northern pattern. The arm, being centre-pivoted, does not fall, but jumps out from the post, and turns a somersault, so to speak, in assuming a position quite parallel with the latter [18].

Foreign railways employing semaphores have almost invariably preferred the upper quadrant type [19], in which the arm is moved to an angle *above* the horizontal position for the safety indication. This movement has the advantage of needing no counterweights to make the blade automatically assume the danger position, should any of the fittings fail; while it enables the signal to be placed at a low height above the ground, thus rendering it easier to sight under bridges. The first upper-quadrant type of signal seen in this country was when the Metropolitan Extension Railway was entirely re-signalled on this principle in 1910.

The face of every semaphore signal is painted red, with a white band, spot, or stripe; while the back is painted white, with a black band, spot, or stripe.

Selection of Position of Signals. All semaphore signals are placed in such a way that on approaching them the arm appears on the left-hand side of the post, and, except where the line curves sharply, the signal-posts are kept as far as possible on the left-hand side of the track, in the direction in which the trains travel. When two or more posts are clustered together, controlling several lines of way, the signal on the extreme left refers to the track on the extreme left, and the second to the second from the left, etc. In the signalling of two or three lines of way branching out from a common line at a junction it is, however, usual to bracket the posts, in which case the posts often number in height from the right, the tallest referring to the fast or main line, the next highest to the second line from the right, etc. In the event of the main line being on the extreme left, this procedure, of course, is reversed. At junctions the posts, whether placed separately or bracketed, agree with the geography of the route. Some companies further distinguish the signal arms that refer to the slow or loop lines by giving them hoops. Three or four arms referring to different lines should never be placed one below the other on the same post; each line should have a separate post or bracket.

When the railway is much enclosed by buildings, it is often necessary to employ very high signal-posts, in order to obtain a sky background for the blades. Signals elevated more than 45 feet above rail-level are furnished with a replica arm on the same post, 15 feet above rail-level. The high arm is seen against the sky for some distance away. As the train comes nearer to the post, the high arm grows less easy to see, and the low arm more so.

Signals Under the Block System. Under the *block system* the outdoor fixed signals are divided into home signals (outer and inner), distant signals, starting signals, advanced starting signals, calling-on signals, and backing signals.

All except the "distant" are stop or danger signals, and every stop signal defines a limit for traffic movements. The home signal marks the termination of one block section, and the starting signal the beginning of another, while the space between them—sufficient to take the longest train—is a kind of neutral zone. When, however, the points worked from a signal-box are numerous, and are spread over a considerable length of main line, it may be desirable to subdivide this zone by means of an extra or inner home signal, in which case the home signal first come to is called an *outer home*. The distant signal, which is differentiated from the others by cutting a notch in the end of the blade, instead of leaving it square, is placed in front of the home, the distance depending upon the gradient of the line, but 1000 yards is about the limit. Its function is merely to warn the train that it is approaching a home signal, and it is so interlocked that it cannot be turned to safety when the latter signal is at "danger."

The *starting signal* notifies the driver when he may enter the section in advance, provided that there is no advanced starting signal, but where this latter exists the starting signal only gives permission to go to the *advanced signal*, which is provided for the purpose of allowing a train which has to pass the starting signal, in order to pick up waggons from sidings or to clear the neutral zone, to be brought to a stand without entering the section in advance.

Calling-on and *backing signals* control short shunting movements, either within or just beyond the neutral zone. They are distinguished from other signals by having shorter or skeleton arms.

All semaphore signals project from the left-hand side of the post, and wherever possible the posts should be placed upon the left-hand side of the

line to which they refer. It is not considered safe to place any stop signal in such a position that a train standing at it is out of the signalman's sight, unless some means of indicating the presence of the train is provided in the signal-box. This is mechanically accomplished by means of *train safety bars*—depression bars, which stand normally at rail level, and are depressed by the passage of wheels over them. The depression of the bar is caused to actuate a lock by which the movement of a signal or point lever is prevented as with a lifting bar. Sometimes the depression bar is used to break an electric circuit with the same result.

Again, it is essential that the signalman should know the exact state of signals hidden from his sight by curves, bridges, or other impediments to his vision. Therefore, all signals so situated are furnished with electric repeaters to the signal cabin, which not only imitate the movements of the arm —viz., "on," "off," and "wrong"—but also show "light in" and "light out," one wire only being required for the five indications. In important junction and terminal station boxes several other kinds of electric tell-tale instruments are in use, as, for example, train-starting indicators, which announce when trains are ready to start from the different platforms; and route indicators, which advise which route a train is to take.

Controlled and Slotted Signals. We have said that ordinary signal-arms ought never to be placed one below the other on the same post. Nevertheless, in cases where the block sections are short, it is advisiable to have the "distant" of the section in advance placed upon the home, starting, or advanced starting post of the section in rear, when the "distant" must be the lower arm. Both signals must then be mechanically "slotted" in such a way that the "distant" can never be taken "off" when the "home" above it is "on"; while, in order to avoid the discrepancy of the "distant" showing "off" when the home is "on," the home signalman must be able simultaneously to place both to "danger" as soon as a train passes.

Route-indicator Signal. When one line leads into several roads, as, for instance, at the approach to terminal stations, simplicity combined with economy in signal posts, arms, and lamps is effected by employing a *route-indicator signal* [22], consisting of a single arm, and below it either a numeral route indicator or a destination board, which is illuminated at night.

Some Minor Signals. Either small disc ground signals or dwarf semaphores [21] are generally employed to indicate the position of the points at a cross-over or at the entrance to sidings. The former signal is a disc of metal, with a lamp carried on a spindle, which turns on its axis. The position of the disc by day and the colour shown by the lamp at night furnish the necessary indications as to which way the points are set.

Indications at Night. In the case of semaphore signals these are given by two differently coloured glasses, through one of which at a time the light of a lamp shines. The coloured glasses are contained in a "spectacle frame," which moves in unison with the signal-blade. A red light indicates "danger" and a green light "safety." No other light is allowed in the case of stop signals for the following reason: If a coloured glass falls out of the spectacle frame the light is shown white, and a driver knows that something is wrong; whereas, were red and white lights used, the falling out or breakage of the red glass might not be detected, because a driver would take the white light for a genuine safety signal.

A problem which has not yet been satisfactorily solved is how to distinguish in the dark a distant signal in the "on" position from a stop signal, as both show a red light. Some years ago the London and North-Western Railway adopted a purple light for the distant signal, but after a longish trial abandoned it. In the United States they use an orange light for the distant signal, and this was recently adopted by the Metropolitan District Railway. When the orange light is employed, it is customary to colour the blade of the semaphore orange, with a black band or stripe, instead of red, with a white band or stripe.

Some companies employ a patent lamp having a copper extension, in which is inserted a ground-glass "fish-tail." The lamp, therefore, exhibits the "fish-tail" mark on the right of the usual light, and the distinction can be sighted 250 yards away. The latest device is, however, a red flash-light.

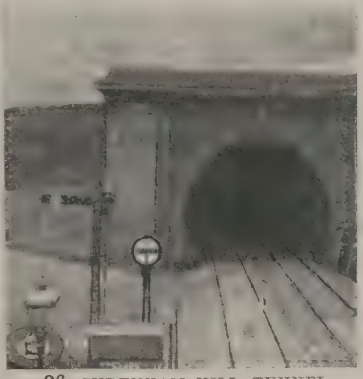
It was formerly the custom to use red and green lights with every variety of ground point-signals, but a number of railway companies for some time past have substituted a small white light for the previously existing red light in such signals as ground discs, siding, and backing signals. The object of the change is to prevent confusion between main and subsidiary signals, and to improve the appearance of station yards at night from a driver's point of view, and it is claimed for it that in the event of a red lamp being exhibited on occasion of emergency the possibility of its being observed and acted upon is much more likely than on those lines where red lights are provided for the ground signals.

Restricted Speed Indicators. Speed restrictions, imposed round sharp curves, through junctions, or for other reasons, are sometimes not too seriously regarded by drivers, owing to the general absence of a warning board, while when the latter is provided it is rarely illuminated at night. To remedy this omission the London and South-Western Railway began to install day and night *restricted speed indicators* in 1911. The first indicator, which is fixed about a quarter of a mile ahead of the point where the restriction of speed begins to take effect, carries numerals representing the number of miles per hour to which the speed is restricted. The next post, carrying the letter "C," indicates the point where the speed restriction begins, and a third post, carrying the letter "T," marks the point where the restricted speed ends and normal speed may be resumed. The face of the lanterns is made of translucent glass, with the numerals and letters painted upon it. Behind the glass are two long-burning oil-lamps, kept continuously burning. By day the white glass forms a good ground for the black figures painted on it, and by night the light of the lamp forms an equally bright ground.

Interlocking Signals and Points. But the fixed signals do not do more than direct train movements. To turn a train off one line of way and on to another connecting with it, a pair of tapered movable rails, called *switches* or *points* [29], are utilised. If these points lie towards a train they are termed *facing points;* if in the reverse direction, *trailing points.* [See page 2963]. Facing points are to be avoided as much as possible. Thus, a train generally enters a siding, or crosses from one line of way to another, by means of trailing points—that is to say, it backs. Both signals and points are actuated from a signal cabin, and, in order to

prevent contradictory movements on the part of each, the signal and point levers are concentrated in one frame, and mechanically interlocked. Consequently, the locking frame [30] of an important signal-cabin is a wonderfully complex piece of mechanism.

Among the refinements that tend towards the perfection of interlocking, mention must be made of the following. The *locking bar* is a long, flat bar lying along the edge of a rail and close to a switch. Each time the switch is moved this bar must be raised above rail-level. Thus, a train travelling through the points is master of the situation; not even the signalman can either intentionally or inadvertently change their position. The *detector lock*, if, owing to a broken rod, the points have not been moved, prevents the signalman from lowering any signal which would be contrary to the actual position of the points themselves. The *facing-point lock* ensures that the points are properly set close home to the stock or fixed rail; otherwise the road cannot be signalled clear. The *clearance bar* consists of a series of locking bars, placed between the starting signal and the signal-box, and so long as a train is standing upon one of them the block instrument and home signal are automatically locked at danger, and a signalman is unable to commit an error should he have forgotten the presence of the train in question.



26. SYDENHAM HILL TUNNEL ELECTRO-MECHANICAL SIGNAL

Manual Operation of Signals and Points. Signals are worked by wires, and the points by rods connecting with their respective levers. Levers are of sufficient length to enable the signalman to manipulate them with moderate exertion, but, where signals are placed at long distances from the levers controlling them, counterbalance weights are provided both on the lever and on the signal-post to assist the operator. It should be added that the Board of Trade limits the distance at which trailing points may be manually worked from a cabin to 300 yards, and that of facing points to 250 yards.

27. TRAIN TRIP ON THE METROPOLITAN DISTRICT RAILWAY

The Signal-box. Great care is taken in the design of signal-boxes so that they shall be light and airy, and give those in charge a clear view of the track from every point. A gallery often runs along the front of the box, so that the signalman can go out to transmit messages to engine-drivers, guards, shunters, and others, without losing audible touch of his electric bell instruments. Every lever in the frame is numbered, and on the floor beside it or on a board in front of the frame there is fixed a brass plate engraved with its name and use—namely, "Up home," "Down advanced starting," "Main line cross-over," and so on. Sets of levers are distinguished by being painted in different colours below the handle and spring catch. The following is the standard colour arrangement: red for home signals, green for distant signals, black for points, white for spare levers, and fancy hoops for anything out of the ordinary. In junction boxes it will be further observed that many levers bear an array of numbers, sometimes a dozen or more. These numbers form the key to the interlocking. Before any numbered lever can be moved, each of the levers to which the numbers on it refer has to be pulled over in the order in which the numbers run. Above the lever-frame hangs a shelf, on which stand the block telegraph and bell instruments, repeaters, route indicators, telephones, and similar instruments, and above the shelf is displayed a large chart of the tracks, sidings, switches, cross-overs, and fixed signals controlled and operated from the cabin.

28. ELECTRIC CAB SIGNAL (N.E.R.)

Block Working with Three-position Instruments. The standard practice of absolute block working with three-position instruments (two-position instruments are practically obsolete) is as follows: A signal-box is placed at the termination of each section, and is provided with four block telegraph instruments [20], one in each direction for the up and the down line respectively.

On the approach of a train to A, the signalman there will call B's attention by a code of bell-beats, and then give the "Is line clear?" signal of inquiry. The signalman at B, having ascertained that the line is clear between A and B, replies by bell signal in the affirmative, and turns the handle of his block instrument so that the indicator or needle on his dial, as well as that on A's dial, points to "Line clear." The train may then be despatched from A. As soon as the train has left A, the signalman there must give B the bell signal "Train entering section," and B must acknowledge this signal, and unpeg his needle. The signalman at A must then give B the "Train on line" signal, by pegging over his needle to this indication, which causes B's dial to read the same. It is now time for B to call C's attention, and to give him "Is line clear?" signal. When the train has passed B's box, B rings his bell to A and moves his needle to zero, which indication is repeated on A's dial. The line is now closed between A and B, although no train is in it. As soon as the train has passed B it must be signalled as above directed to C, and so on throughout the block sections.

Lock and Block System. If a second train should arrive at a signal-box before the preceding one has been signalled as "out of section," it must be stopped and detained until the message has been received. Theoretically, therefore, there can never be two trains in the same section at the same time. But how are errors like the following to be prevented: B accepting a train from A when the line A B is not clear; A taking off his outdoor signals without asking B if the line is clear, or if to do so is contrary to the directions of his dial? The answer is by combining the block and interlocking systems by means of mechanical or electrical apparatus, so that any one signalman is rendered powerless to perpetrate errors, his actions being controlled either by the signalman on each side of him or by the train itself. This is known as the *lock and block system*, and it is usually dependent for its action in controlling the "line clear" indication on either a rail treadle or a rail contact, operated by passing trains. Nevertheless, this particular system has its weak points. "The depression of the treadle," writes Mr. C. B. Byles in his "First Principles of Railway Signalling," "is not an infallible signal that the section is clear, but merely that a vehicle of some sort, which may have come from a siding, has passed over it. Then there is the problem where to place this treadle. If placed too far ahead it is not actuated by trains which may have been shunted clear of the main line, and if placed too far back it is actuated and clears the section too early, as, of course, it is operated by the first wheel which passes over it." It is a confession of unreliability that it should be found necessary in all lock and block treadle systems to provide means whereby the signalman can himself effect release of block instruments independently of the train. Otherwise a man is liable to get himself locked up owing to signalling a train forward on the block instruments, which is shunted or cancelled, or perhaps some part of the electrical apparatus may not work exactly owing to tight adjustment. Therefore, it is necessary to provide a releasing key for the man to unlock himself, and herein lies the danger of a man making improper use of the key. This point has, however, been considerably met by it being necessary in modern lock and block instruments for the signalman on each side to co-operate in the releasing of the key.

Automatic Signalling. Automatic signalling, whereby the train provides for its own safety, has been perfected but recently, though it began to exercise a fascination for inventors at an early period. After many attempts, it was found that the ideal solution of the problem lay in track, or, more correctly, rail circuits. The London and South-Western Railway in 1902 was the first to install a long series of track-circuit automatic space signals [25]. The principle is as follows:

A low-tension current flows from a battery along one rail of the track through a relay, and back to the battery along the second rail. The relay makes and breaks a local circuit, which by means of electromagnets controls the mechanism, electric or pneumatic, or whatever it may be, for operating the signals. When the current is flowing along the line the relay completes the local circuit, and the signal is held "off." When, however, a locomotive or other vehicle with metal wheels and axles is in the section a short circuit is established in the track circuit, the relay becomes inoperative, the local circuit is broken, and the signal returns to "danger." By insulating the rail-joints at intervals the line is divided into sections, to each of which a separate current is supplied. Track-controlled automatic signalling installations, as a rule, revert to the normal "clear" position of signals; but the Hall system, installed on the North-Eastern Railway [24], conforms to the standard block regulations, keeping the signals at danger while the line is closed. With the Hall system, given a clear line, the train is made to take off the signals on approaching each successive block section. The track-circuit system is common to all modern installations of automatic signalling, though the signal movements themselves may be actuated either pneumatically or electrically, or by other means. The Hall system employs compressed liquid carbonic acid gas for energy, and the self-contained gas-motor possesses the advantage of obviating the use of separate batteries, air-compressing plant, pipe-lines, etc. Track-controlled signals convey a guarantee that the track itself is in good order, for, should a rail break, the danger signal would be given. If a permament-way man finds anything wrong with the track he can block the line at once by short-circuiting the rail-battery, with a crow-bar, or any metal tool of sufficient weight.

Illuminated Diagrams. By means of track-circuits the diagrams ordinarily used in signal-cabins, showing all the lines, sidings, junctions, and signals, can be made much more realistic. They can be converted into illuminated diagrams [23], which tell the signalman what lines are occupied, when connections are fouled, and when trains are approaching. These diagrams are painted on glass, which is opaque all over, except the roads. Electric lamps are placed behind the roads in the diagram, and are partitioned off in lengths to correspond with the track-circuit block sections; they are so controlled by the track-circuit relays as to be always alight, except when the circuit is opened, owing to the presence of a train in section, when the lights go out, and so advise the signalman that the section is occupied. Such an arrangement has proved indispensable on the Metropolitan District Railway and tube railways, where the signalmen are unable to see the points or roads they control, and it is now being adopted in large stations and shunting-yards where fogs are prevalent and much night work has to be carried on.

Advantages of Track-controlled Signals. Other advantages of track-controlled signals are as follows: Augmented track-capacity, for they enable a greater number of trains to be passed over a given stretch; uniform running of trains; a guarantee that the section is really clear. The wonderful frequency and regularity of the electric train services on the underground railways of London is only rendered possible by signals of this type, and the system as at present arranged allows trains to follow one another at an interval of eighty seconds, and even less. Although this method of signalling cannot be employed at junctions, the frames of these signal-boxes can be so arranged that for straight-through traffic the levers controlling the main-line signals can be pulled over and the box closed, resulting in automatic main-line signalling through a junction.

Train-stops. Where rail-circuit automatic signalling is in force there is but one loop-hole for error on the part of the human equation—the driver may nullify all its safeguards by disregarding the signal to stop. Inventors are now trying to solve this remaining problem by means of the trip or train-stop. Up to the present all such apparatus have taken a mechanical form, a ground arm or trigger, which acts in unison with the signal. When

30. SIGNAL-BOX WITH A SIXTY-FIVE LEVER-LOCKING FRAME AND ELECTRIC TELEGRAPH BLOCK INSTRUMENTS AND BELLS

the latter is at "danger," the ground arm stands in a position which causes it to engage with a cock on the brake-pipe at the head of the train, thus automatically applying the brakes if the driver overshoots the signal. Train-stops of this description are in use by the underground railways of London and other electrically worked lines [27], but the trip arm on the coaches will only act if it be set properly. The practice is for the arm on the leading motor-vehicle to be set on departure from the terminus, which, of course, means that the process has to be repeated at the end of each journey, when with motor-trains the last vehicle becomes the first on the return journey. Failure to observe this precaution will cause the train-stop to become inoperative. At the time of writing, a train-stop applicable to conditions of steam traction does not appear to be invented.

Track-circuits and Safety. The scope of track-circuits is, however, far from being confined to rendering the fixed outdoor signals automatic. In lock and block working they may be substituted for treadles between the home and advance signals, thus removing the only weak feature, as already alluded to, in an otherwise excellent method for protecting trains. They also better fulfil the functions of "train-protection bars," and other mechanical or semi-mechanical devices for placing a check upon the actions of signalmen, and rendering it unnecessary that, in accordance with Rule 55, the fireman or guard of a detained train should go to the signal-box to remind the signalman of the position of the train or engine. The Midland Company has gone in largely for track-circuit protection, and where it is installed its signals now bear a white enamelled diamond-shaped board just below the arm. This signifies that no one need go to the signal-box to remind the signalman. But where a plunger is provided at the signal-post, which the fireman can actuate instead of going to the box, the post bears a board shaped thus: . Where there is no indication the fireman, guard, or shunter, as the case may be, must go to the box in accordance with Rule 55. The utility of track-circuits also extends to *approach locking*—namely, the presence of a train in section can be made to hold points at any required distance ahead until the train has passed over them. To sum up, track-circuits unquestionably form the most important contribution towards the attainment of safe railway working yet devised.

Power Signalling. Various systems of "power signalling," so called, have come to the fore since 1896, enabling signals and points to be operated by some form of power, instead of by the manual force of signalmen. Early in the 'seventies Mr. W. R. Sykes took out the first patent for operating signals by power, and in 1875 he installed the first power-worked (electrically) signals in the world, at the entrance to the Sydenham Hill Tunnel on the Chatham Railway [26]. The first large power interlocking plants were, however, those set up (in 1897) at Spitalfields Goods, Great Eastern Railway, and at Crewe. As with the manual system, it is necessary to have levers interlocked with each other, and with some power systems the mechanical levers are retained in miniature, hence the signalman has nothing new to learn in the way of movements. The interlocking frame of a power installation, of course, is much smaller and more compact, and it is possible to interlock points and signals by return connections to the levers. Therefore, the signalman, after moving a lever, is made aware whether the point or signal has answered the lever. It will be understood that the result of pulling or releasing a lever is merely to transmit power for the purpose of actuating a motor adjacent to the points or signal itself, this motor performing the required movement of the points or signal. The connections between the signal-cabin and the motors are invariably laid underground, thus eliminating the risk of employees tripping over exposed gear, in the form of wires and rods. Moreover, with underground connections, the mechanism itself is less liable to accident, neither can it get clogged with snow, ice, or dirt.

Train-movements can be carried out much more rapidly by means of a power installation than with a manual plant. With the former the levers are nearer together, and the physical effort of moving them is infinitesimal. Also it is claimed that the automatic return indication relieves the signalman of mental strain, so that not only can one power signalman do the work of three manual operators, but he does it with less expenditure of nervous force. The Board of Trade permits facing points to be worked by power from a greater distance than manually. But while power signalling effects a considerable saving in working and maintenance expenses, the higher initial cost precludes its adoption except at very busy centres. Among the different systems now in use are the McKenzie-Holland and Westinghouse electro-pneumatic (normal pressure), installed on the Great Eastern, North-Eastern, Caledonian, Lancashire and Yorkshire, and Metropolitan District railways; the electro-pneumatic (low pressure), used by the London and South-Western and Great Central; the "Crewe" all-electric, employed by the London and North-Western; the Siemens all-electric, adopted by the Great Western; and the Sykes electro-mechanical, found on the Brighton, South-Eastern, and Glasgow and South-Western railways.

Power Signalling on a Large Scale. The signalling of the Glasgow Central Station, Caledonian Railway, may be described as the most up-to-date example of power signalling upon a large scale. This vast traffic centre is controlled from one signal-box [36], which was brought into use May 3, 1908. The locking frame is 83 ft. long, and contains 374 levers, which is larger than any purely mechanically or purely power-worked frame in the world. The system is the McKenzie-Holland-Westinghouse, in which the points and signals are actuated by motors operated by air compressed to a pressure of about 70 lb. per square inch, the valves of the motors being opened and closed electrically by circuits controlled by the movements of small levers in a miniature locking frame. The points are actuated by the usual electro-pneumatic method—the switches, plunger, and locking bar all being worked by one movement, the full stroke of the lever not being attainable until the return indication has been obtained that the lever has done its work.

In addition to this there has been provided a further safeguard by the introduction of "constant detection." The virtue of "constant detection" is that a signal cannot be cleared, or, if cleared, is put to danger by the disarrangement of the points due to any cause after the points have assumed a proper position by the movement of their respective levers. This is accomplished by a special electro-mechanical device forming a part of the point-lever mechanism working in conjunction with detecting apparatus situated at the points and in direct connection with the levers themselves. If a pair of points is trailed through, rendering them

unsafe for traffic, or if their position does not correspond from any cause with that of the lever by which they are controlled, the device above referred to operates so as to put the signal to danger, if it has been previously cleared, or to prevent the signal being cleared in case its lever should be operated.

Route Indicators. A large reduction in the number of signal-arms has been obtained by the use of route indicators, which bear upon them the number of the platform or road. Under the arms or by the side of the posts is a case containing slides, all of which bear numbers corresponding to those of the roads the signal leads to. The case also contains a shutter, which is normally down when the signal is on. For instance, from No. 3 down line it is practicable to run into nine out of the thirteen platforms of the station, but there is only one arm. A train wishes to be admitted to one or the other of the nine platforms. The signalman would first "set" his road for the selected platform, and then pull over the corresponding lever, which would cause an electric current to flow to the indicator case and withdraw the lock from the slide bearing the number of the platform in question. The current would flow to the magnet of the motor which would cause the slide to be lowered, and then to the motor that would lower the arm and raise the shutter. If the platform were not fully clear, the signalman would pull over the lever, which would lead to practically the same movement, except to lower the arm.

Fog-signalling. We now turn to the problem of signalling during foggy weather and falling snow, when the outdoor signals are obscured from vision. A primitive procedure, still very widely practised, consists of stationing men at the signal-posts to place detonators on the metals, the explosion of which, under the leading wheels of the engine, tells the driver of a "danger" indication. The *detonating fog-signal* was first introduced by Mr. E. A. Cowper, M. Inst. C.E., somewhere about 1841 or 1842, and in 1844 it was recommended by General Pasley, Inspector-General of Railways, for general adoption. This signal now consists of an outer and inner dome of tin and a circular base-plate. On the base-plate in the centre is soldered a triangular-shaped piece of metal, on which are three nipples. Percussion caps are placed on these nipples to fire the charge of black powder. A recess for the nipples obviates the danger of premature explosion. There is also a duplex detonator, with two separate explosive chambers, absolutely independent of each other, rendering it no longer necessary to place two signals on the rail as a precaution. The detonator is bound to the rail by a strip of tin.

31. TRACK RAMP FOR CAB SIGNALS

Fog-signalling with hand-placed detonators is rather a fallible device, and a risky occupation to boot. To facilitate the work of the "foggers," it is usual to have miniature signals on the ground, which are mechanically or electrically connected to the real arms.

Fog-signal Pits and Machines. Some lines, notably the Great Eastern, have tried sinking pits between the tracks at busy places, and placing the signal repeaters and fogmen in them. This was, however, found dangerous to the men, in that the detonators exploded on a level with their faces.

Many types of fog-signalling magazine machines have been placed on the market, designed to render it unnecessary for the fogmen to cross the rails in order to place the detonators on the line he is signalling, and at the same time to facilitate the fogging of two or more lines by one man should circumstances allow. Of this type is the "Premier" machine, supplied by the Railway Signal Company, with a capacity for exploding eighty or more detonators as required without recharging. The detonators are placed under a punch, which is fixed on the outside of the rail, and is slightly raised above rail-level by the detonator being placed under. This operation is done by pulling the lever over. The tyre of the wheel depresses the punch, and so explodes the detonator. Frequently the cause of the failure of a detonator to explode is traced to a skidding wheel, which pushes the detonator off the rail. By this invention the detonator is not placed on the line, and consequently that danger is removed. The exploded detonator is removed from under the punch by the man placing the lever in the normal position, and a new detonator is automatically placed in the holder at the end of the stroke of the lever. Should, however, the detonator not be required for explosion by the train for which it was placed, it can readily be removed by the lever being placed in the mid-position, and can be placed under the punch a second time, when desired.

However, fogs and snowstorms are apt to come on suddenly, and between the time when the fogmen arrive on the scene there is the risk of drivers running past danger signals, in default of hearing a detonator explode. To meet this danger, an apparatus has been devised whereby a signalman can place a detonator on the line without moving from his box. Automatic fog-signalling machines on these lines are now installed on the District Railway. They are worked by air motors in accord with the automatic track-controlled signals. In normal working the apparatus is out of use, but it is switched into play from the nearest station directly a fog comes on. The magazine contains fifty detonators, and when the stock drops below a certain limit the machine starts whistling to be replenished, and continues its lament until its needs are attended to.

Engine-cab Signalling. But, when all is said and done, the most efficacious solution of the fog and other kindred problems is some method of automatically repeating the indications conveyed by the outdoor signals direct to the cab of the locomotive, where the enginemen cannot fail to see or hear them. Till comparatively recently all of the many inventions which aimed at achieving this object sought to do so by purely mechanical means, such as fixing a lever alongside the track, so that while the corresponding signal stood at "danger" it would catch against an arm projecting from the locomotive, and the resultant impact would cause either a bell to ring or a whistle to blow, or would actuate a miniature semaphore on the engine. But the weak point of any such system at once occurs to the mind. The force of the blow set up by such a weighty body as a moving train is so tremendous that the pedals or triggers thus arranged are liable easily to be thrown out of gear.

Electric Cab-signals. That the best solution of this difficult problem is by recourse to electricity was realised some years ago. One of the first apparatus embodying this principle was Boult's *induction cab-signal*, which was tried on the Great Central Railway about fifteen years ago. Its essence was the establishment at the side of the line of a magnetic field, proportioned in length to the average speed of the trains passing the spot. An armature attached to the locomotive was carried through the magnetic field in the close neighbourhood of, but making no actual contact with, the magnets. In this armature there were independent needles, which, being deflected by the electric current set up by the magnets, made a contact, and so rang a bell to call the attention of the men on the footplate. The use of this cab-signal was only discontinued because the line in question was used by the engines of other companies who objected to fitting their engines for it.

An ingenious and reliable cab-signal of the audible type [39] has lately been adopted by the Great Western Railway, where it is used, by permission of the Board of Trade, as a substitute for fixed visual distant semaphores. Under this system the driver receives either a bell ("clear") or whistle ("caution") signal in his cab, instead of having to rely upon sighting the distant signal. Therefore, the system offers the additional advantage of being in constant use, and so guards against possible forgetfulness of drivers even in clear weather. The cab-signals are brought into play by means of a ramp [31] between the rails and a contacting device or shoe carried underneath the engine. Whenever the engine passes over a ramp the shoe is forced upwards. When it is desired to give the "caution" signal the ramp is left "dead"—that is, uncharged with electricity, and the lifting of the shoe mechanically destroys a local electric circuit on the engine, causing the whistle to sound and a red-coloured shutter, inscribed "danger," to appear in an indicator inside the cab. When it is desired to suppress the normal "caution" signal, the signalman moves a special lever in his cabin, which causes the ramp to be energised with electricity. The shoe now picks up current from the ramp, with the result that the "caution" signal is restrained, and an electric bell, indicating "line clear" begins to ring instead.

The outstanding feature of the apparatus is that, as the operation of the "caution" signal from depending upon the raising of the shoe is mechanically infallible, while the suppression of that signal depends upon the successful picking up of electric current, neither dirt, frost, snow, nor electrical failure can prevent the operation of the more important indication. The worst that can happen is for the "caution" signal to be given in error.

The apparatus has stood the test of heavy snowfalls, when it was found necessary to abandon the use of the semaphore signals owing to their being clogged with snow. Some of the engines fitted with the apparatus have a hollow arm, which can be heated by steam to melt snow and ice congealed on the ramp.

Another ingenious cab-signal has been adopted by the North-Eastern Railway [28]. It is the invention of Mr. V. L. Raven, the company's chief mechanical engineer, and is designed to pick up indications by the rubbing of metallic brushes carried on the engine over metallic bars placed in the track. This method of collection, however, is not essential to the system, since it is capable of acting equally well without direct contact, by causing electro-magnets on the line to influence magnets on the engine. The system employs both visual and audible cab-signals. The former are conveyed (1) by a miniature semaphore, whose position indicates the condition of the line ahead as shown by the home and advance signals; (2) by two needles, deflecting to numbers 1 and 2 and 3 and 4 respectively. These latter are route indicators, and inform the driver which road he has to take at a diverging junction of four ways or less. Thirdly, there is a failure indicator in the form of a small grid, through which a white light shines whilst the system is in operation, and a red light if it fails or is cut off. The audible signals, which are merely to call attention, are given by a bell. The line "distant" signal plays no part in the system, and may be dispensed with if desired, for the electrical signalling point can be installed at any distance from the signal-cabin. On the route indicators a straight-through point is signalled as Number 1. If, while a train is halted at the home signal, the signalman wishes the driver to draw up close to his box in order to speak to him, he can so manipulate his levers that the cab semaphore will work up and down, and the bell ring intermittently. This cab-signal has been in use for several severe winters without experiencing any difficulty from ice. It was originally an "open circuit" system, but is now a "closed circuit" system. The action of the apparatus is of the simplest possible character, the main principle being the invariable operation of the apparatus at certain points, by the natural action of certain parts, without the aid of either signalman or driver, and the subsequent continuance of the indications resulting from the natural operations, until they are stopped or reversed by the action of the signalman.

The Richmond branch of the North-Eastern Railway has recently been equipped for cab-signalling, and it has been arranged that upon this branch no engines other than those fitted with the Raven apparatus shall run.

Staff and Tablet Working. The regulation of the traffic on single-line railways is accomplished either by an electrical train staff or tablet apparatus. A staff or tablet, suitably inscribed, is delivered to the engine-driver at station A, and constitutes his authority to occupy the main track between A and B. On reaching B, he surrenders the tally, and receives another one, which gives him the right to the road between B and C. The tallies, in any desired numbers, are kept at each of the two stations, and are locked in a cabinet, automatically controlled through electromagnets, by an apparatus in the cabinet at the other station. And, a staff or tablet being taken out at one station, a second one cannot be taken out at either station until the first one has been returned to the magazine at one station or the other. Thus, to get two trains in the same section at the same time is impossible. One line wire is sufficient for all purposes—namely, operating the staff or tablet instruments, giving code signals on bell, and for telephonic communication. When it is required to work permissively a single line equipped with the staff apparatus the following method can be adopted with perfectly safety. Each staff can be made up of three portions coloured distinctively. The end portions, coloured red and blue respectively, are denoted as "tickets"; while the centre and fundamental portion, coloured yellow, is called "staff." When it is desired to send three following trains from station A to station B, an entire staff is withdrawn from a magazine [37] in the ordinary manner. The first and second driver each take a ticket and see the staff. The third driver

will take the staff. It is physically impossible to replace the staff in either instrument until the three portions are screwed together, and until this is done both instruments remain locked.

Exchanging Apparatus. On some lines, in order to avoid stopping at signal-boxes to discard one tally and pick up another, what are called staff "catchers," or tablet "snappers," are employed. A "catcher" [32] usually denotes an apparatus for exchanging the full-sized staff instruments, which are especially equipped with ring-handles. It is a very simple contrivance. By the side of the line is fixed a post, with an arm projecting to the driver, and shaped to receive the staff for the section the train has just passed through. A driver hangs the staff by its handle on to this arm, which projects from a leather-padded target, in order to absorb the force of the blow. A few yards farther on is another post with a pocket [33], into which is placed the staff for the section in advance. The driver plucks his staff as he passes the post. At night the target-arm and fresh staff are made prominent by means of lamps, carried on a separate post in the case of the former, and braceted to the second staff-post. With this exchanging contrivance a train need slow down to only 20 miles per hour.

It has long been customary to exchange electrical train tablets, which are small metal discs, at higher speeds by hand. The tablets are placed in leather pouches furnished with wire hoops, and through the latter the driver and signalman respectively thrust their arms as the train speeds by. But the practice is a somewhat risky one, hence several automatic tablet exchangers have been devised.

Whitaker's Tablet Exchanger. A very ingenious "exchanger" [38] has been invented by Mr. A. Whitaker, and is in use on the Somerset and Dorset, Midland and Great Northern Joint, and Colonial railways.

The locomotive tender is equipped with a catcher which slides in and out in a bracket, and is thrown out when it is required either to catch or discard a tablet. The aluminium tablets are placed in leather pouches furnished with rings. By the side of the track are placed columns having one or two different kinds of arms, according to whether the column in question is for setting down, picking up, or exchanging tablets. If the last-named, two arms are necessary, the upper one being the setting-down arm, and a replica of the fish-tailed catcher on the tender, the jaws of which have three triggers. A tablet to be discarded is carried in a slot at the back of the tender catcher, and is snapped off by the ring passing through the jaws of the catcher by the side of the track, while a tablet to be picked up is hung from its ring on another arm, and snapped up by the tender catcher. The arms normally stand in—that is, are parallel with the track—and when to be used are thrown out by levers. An outstanding feature of the apparatus is, however, the automatic return of the arms to the normal position directly the process has been effected. Otherwise, the fact of the arm being left to project diagonally so close to a train would be attended with serious risks. The "snapper" performs its work at a speed of sixty miles per hour.

In one particular instance, however, it was not found practicable to place a receiver by the side of the track; it had to be located in the six-feet way, thus necessitating a special design. With this type of receiver the arm is set vertically [34 and 35] for an approaching train, and drops down vertically —backwards—instead of revolving horizontally, directly the catch off the tender is effected.

In many cases, by the use of electrical train staff and tablet instruments, together with exchanging apparatus, the facilities for working the traffic are so improved that the doubling of single lines and the consequent capital expenditure has been indefinitely postponed.

The Training of Signalmen. As a rule, the selection of candidates for the post of signalman, together with the training and allocation of signalmen, rests entirely with the traffic department. The practice observed in the main by all companies is to appoint youths between fourteen and sixteen years of age as lad porters, and those among them who wish to become signalmen are encouraged to learn single-needle telegraphy. Again, a lad between the ages named may join the company's service as telegraphic messenger, earning between 6s. and 14s. per week, and at once devote himself to learning the use of the single-needle instrument. A sharp lad will be able to receive and transmit telegraphic train messages in from four to six months' time, and when he has demonstrated his ability he is placed in a large signal-box to act as telegraphist or train boy. Here his duties are to read and transmit telegraphic messages, and to write up for the signalmen the train books that record the times at which every train is accepted into and clears the block section. While acting as train boy, a youth soon gets thoroughly acquainted with the working of the block telegraph instruments, the diagram of the line, and interlocking. Some companies keep train boys until they attain twenty years of age, and then allow them at once to pass the examination by the district superintendent for promotion to third-class signalman. Others, however, relieve the lads of their duties at seventeen years of age, and compel them to revert to porters, lamp-men, shunters, or clerks for a period of three or four years. This latter rule holds good with companies which will not appoint a man a signalman until he attains twenty-three years of age.

When a man who has not previously acted as train boy, or learnt single-needle telegraphy, wishes to qualify for a signalman, he is not allowed to take any steps to carry out his desire until he has been in the company's service for a period of six months. The procedure is then to despatch him in his original capacity, as porter, shunter, or clerk, to some small station, where his ordinary duties are sufficiently light to enable him to learn the practice of signalling and single-needle telegraphy. It is not every company that insists upon the would-be signalman qualifying as a telegraphist, but a man not so qualified could never hope to rise above the rank of third-class signalman on a remote branch line. The same procedure is observed by the companies alluded to above, which do not allow train boys or boy telegraphists to continue as such till they come to the limit of age for promotion to signalmen.

The Complete Signalman. Having acquired a fair knowledge of signalling in a way-side signal-cabin, an aspirant is promoted to a more important station, where, besides fulfilling his ordinary duties, he is put on to relieve for a few hours at a stretch a fully fledged signalman. Lastly, when a vacancy occurs, a man who thinks he has mastered the subject may apply to be examined for third-class signalman, by the district traffic superintendent or signalling inspector, according to the company's practice. The examination is of a searching character. It generally comprises both oral and written examination

in the working of the block system, any patent method of signalling, such as the "lock and block" and electric train staff or tablet system, which may be adopted by the company in question, and "emergency" signals, or what to do in a dozen or more different kinds of mishaps.

Signal-boxes are classified as belonging to principal main lines, secondary main lines, and branch lines. In each of these divisions there are three different grades of signalmen—namely, third, second, and first class; and with some companies there are two higher grades on principal main lines —namely, "special" and "extra special."

Pay and Promotion. The rates of pay vary not only according to class, but also according to division. Thus, a third-class signalman on a principal main line earns more than a first-class man on a secondary main line. Signalmen earn from 18s. to 25s. a week, and receive for correct working a bonus of from £2 to £5 per annum. All vacancies are posted among the men, and each man has a chance of applying for promotion, which is decided by seniority and merit. When a man is promoted to a fresh box he is allowed a fortnight or so in which to learn it to the satisfaction of his superintendent before taking charge. Each signalman is responsible for his own block telegraph instruments, and his first duty after signing on in the train register book is to satisfy himself that all the electrical instruments, signals, and points are in good working order. An adjusting apparatus enables him to adjust his signal-wires for expansion and contraction from heat or cold without leaving his cabin, while the *point-rod compensator* automatically compensates the rods which actuate the points. The signalman is responsible that his signal lamps are lighted and extinguished at the regulation hours and that they are lighted in foggy weather or during falling snow, but the lamps are trimmed, placed in position, lighted, and extinguished for him by porters or lamp-men.

A signalman's hours are never longer than twelve, and that only on unimportant branch lines, from eight to ten hours being the rule elsewhere. Where the work is heavy more than one man is put in a box, and when the telegraph work is heavy a telegraphist also is allowed. The stationmaster supervises the duties of the signalmen at his station, and must frequently visit the signal-boxes for the purpose. Every signalman is examined from time to time in all emergency working by his stationmaster and inspector.

Railway Signalling School. In order to give every employee who so desires an opportunity of acquiring a knowledge of signalling and outdoor railway working, and to avoid the necessity of men going into signal-boxes for that purpose, several companies have established signalling schools. The equipment of these schools comprises a model railway, with main and branch lines, junctions, refuge sidings, cross-over roads, etc. This model railway is fully signalled and provided with facing-point locks and bars, fouling bars, discs, detectors, and other equipment. The whole of the signals and points are worked from a lever frame, properly interlocked. There are complete sets of train-signalling instruments and single-line electric train-token apparatus connected in pairs. These schools are placed in charge of an instructor, who conducts classes.

Department of the Signal Engineer. When men are promoted from being signalmen, they usually go to the traffic department, becoming platform inspectors and rising to district traffic inspectors. The maintenance of the complicated array of signals, interlocking apparatus, and electrical instruments is a work of great magnitude. It is entrusted to a signal engineering department, which has nothing to do with the training of signalmen or manning of the boxes. The work of the department is divided into a mechanical and electrical side. To begin at the bottom, there are signal and telegraph linemen, who are responsible for the maintenance of a certain number of boxes, which they visit periodically according to roster. The signal linemen clean and oil the fittings of each signal and point, and execute any small repairs or renewals that may be required, but they are not allowed to tamper with the interlocking apparatus or to take in hand any important repairs or renewals. Signal fitters come round at less frequent intervals to overhaul, test, and clean the interlocking frames, facing-point locks, and other parts, while heavy repairs and renewals are carried out by an extra gang attached to each district, in charge of a responsible foreman. The telegraph linemen, however, are considered competent to overhaul the block telegraph and all other electrical instruments, in addition to recharging the batteries and mending broken circuits. These men maintain the Post Office wires under an agreement between the Post Office and the railway company. For the purpose of maintenance the whole line is divided into districts, each of which is in charge of both a telegraph and signal inspector. A special department often exists for carrying out new works, under the superintendence of a new-works inspector, who acts directly under the head office. The whole organisation of maintenance is vested in a managing staff, which comprises electricians, draughtsmen, assistants, and clerks, all of whom are employed under the control of the chief of the signalling department.

Railway Brakes. A fact little realised by ordinary railway passengers is that the attainment of the present high speed of our trains was made possible only by inventions of suitable means of controlling them. In itself, the ability of trains to travel at high speed would have been not only a useless but a dangerous thing had it not been accompanied by such improvements in railway brakes as enabled drivers and guards to control the tremendous energy set up by heavy trains travelling at high velocities.

The history of railway brakes is a long and complicated one, which cannot be related here. Suffice it to say that the continuous automatic power brake, the compulsory equipment of which to all passenger trains was brought about by the Railway Regulation Act of 1889, was gradually evolved from the hand-operated screw brake that formed the earliest method of retarding the motion of trains.

The basis of a continuous automatic power brake is an apparatus fitted to each wheel of every vehicle composing a train, so that every engine, tender, and vehicle has its own store of brake force ready for instant use, while its action is such that, if every or any coupling in the train separate, the brake of each vehicle is automatically and instantaneously applied. The brake is capable of application by the engine-driver and by any of the guards.

Unfortunately, British railways have been unable to agree upon uniformity of brake system. At the present day 59 companies are returned as using the automatic vacuum, and 17 companies the Westinghouse automatic air brake.

The "Ordinary" Vacuum Automatic Brake. This brake stops the train by the application of brake blocks to the tyres [40] in the same way as the ordinary hand brake. The levers, however, which apply the blocks are moved by a piston working in a cylinder, the piston deriving its power from the pressure of the atmosphere. It is continuous, each vehicle carrying its own brake cylinder, which is connected to a pipe running from end to end of the train, and through this pipe the action of the brake cylinders is controlled on the engine. A combination ejector consisting of two ejectors known as the "large" and the "small"—the latter being placed inside the former, and worked continuously, while the "large" is worked by the admission of steam—exhausts the air out of the continuous pipe and the cylinders. The brake is applied by the admission of air into the train pipe, and released by the withdrawal of the same through the ejector.

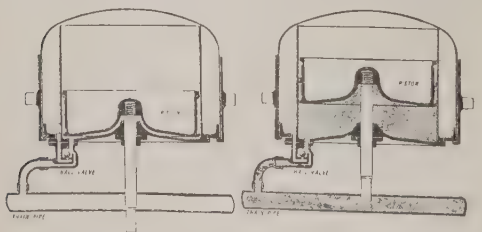
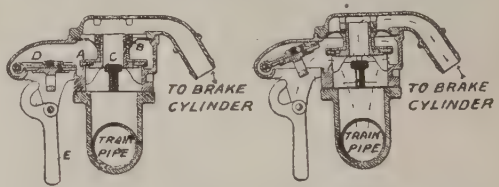
41. VACUUM AUTOMATIC BRAKE

The engine having been coupled to the train, and the hose couplings connected between the tender and train, and also between the coaches, and the one at the end of the train having being placed upon the plug, the driver admits steam to the small ejector, which soon exhausts the train pipe and cylinders to a vacuum of from 20 in. to 24 in., or the large ejector may be used if the vacuum is required to be obtained more rapidly. The small ejector must be kept at work continuously to maintain the vacuum. To apply the brake, the driver moves the handle of the combination ejector in the direction marked "On," thus admitting air to the train pipe and to the bottom of each cylinder, which lifts the pistons and so pulls the blocks to the wheels. The air cannot pass to the top of the piston, as it is prevented by the ball in the ball valve. The power of the application is controlled by the amount of air let into the continuous pipe.



42. VACUUM BRAKE "OFF" 43. VACUUM BRAKE "ON"

To release the brake, the handle must be returned to "Running position," when the air let in to apply the brake will be removed through the small ejector; or it may be released more quickly by pushing the handle in the direction marked "Off," and so admitting steam to the large ejector. The brake having been applied, the pressure of the blocks on the wheels may be increased or diminished at pleasure without removing them, and also without reducing the full reserve power of the brake, which is always at command for an emergency stop.

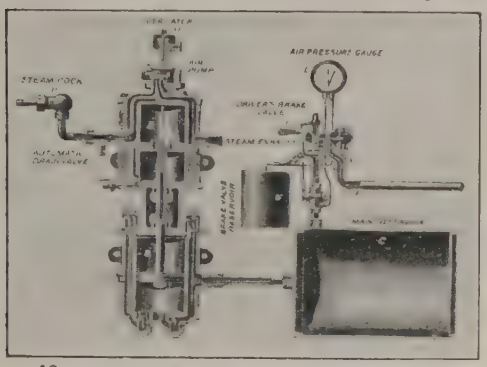


44. NORMAL POSITION OF RAPID-ACTING VALVE 45. RAPID-ACTING VALVE OPENED & BRAKE APPLIED

Ordinary stops should not be made by a violent application of the brake, but by a destruction of vacuum, say, from 5 in. to 10 in., which should be re-created slowly as the train comes to rest by placing the handle in "running position." To apply the brake quickly the handle must be moved to the position marked "On," thus fully opening the air valve [41]. The guard can apply the brake by pressing down the handle of his valve, the "brake setter-valve," thus admitting air and applying the brake throughout the train, which it will stop even if the engine remain under full steam. When a rapid application is made by the driver, the guard's valve opens automatically, letting in air from the van, thus increasing the rapidity of application, and it closes again after the brake has been fully applied.

Arrangement of Brake Cylinder and Vacuum Chamber. The brake cylinder and vacuum chamber is shown in section in **41**, self-contained in the vacuum chamber as applied to carriages, and is the only fitting required. The piston fits freely in the cylinder, and is packed with

a rolling rubber ring, which, when the piston moves, rolls between it and the cylinder, making a perfect packing without friction. The piston-rod is coated with brass and works through a brass bush, and a packing rubber prevents air from passing the rod. This rod should be kept clean by wiping with a dry cloth, but no oil or grease must ever be used. At the bottom of the cylinder is attached the ball valve, the branch of which is connected by a small hose pipe to the train pipe. This valve is of the most simple construction, as there is only one



46. WESTINGHOUSE QUICK-ACTING BRAKE. PARTS APPLIED TO LOCOMOTIVES ONLY

moving piece, and that being a small brass ball, having a rolling action in a horizontal position, has consequently no friction. The spindle with release lever is added for the purpose of withdrawing the ball from its seat when it is required to release the brake by hand—for instance, when coaches are detached from the engine. This spindle is made air-tight by a small diaphragm, the pressure on which when the vacuum is created pulls in the spindle and allows the ball to go freely to its seat

The action of the cylinder is as follows. The air is drawn out through the train pipe from the bottom of the piston direct, and from the top by passing the ball. To apply the brake, the air is let into the train pipe, and it then passes to the under side of the piston, and, being prevented from entering to the top by the ball, lifts the piston, and so applies the brakes with any amount of force according to the quantity of air let in. Fig. **43** shows "Brake on," and **42** shows "Brake off."

A drip trap is placed on the train pipe at the bottom of the down pipe from the ejector, so that any moisture will drain into it. It is fitted at the bottom with a self-acting ball valve, which opens when all the vacuum in the train pipe is destroyed, and allows the water which may have collected to run out.

Before starting, the driver must see that the gauge indicates at least 18 in. of vacuum, and that not less than this amount is maintained during the journey, and while standing at stations. The vacuum is created by admitting steam to the small ejector by means of the steam cock on the combination ejector. The guard also must see by the gauge in his van that the proper amount of vacuum is maintained, or report otherwise to the driver.

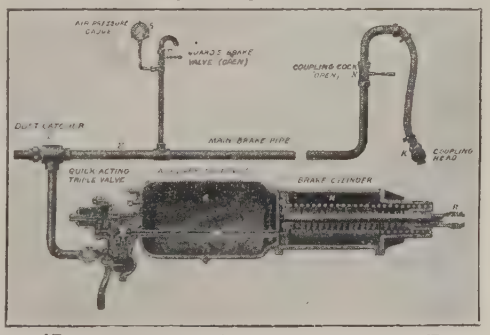
Rapid-acting Vacuum Brake. The rapid-acting vacuum brake—which can be used either as a "rapid-acting" or an "ordinary" vacuum automatic brake—consists of the addition of a rapid-acting valve. This appliance is mounted on the train pipe as near as possible to the brake cylinder, and is connected to the latter by the usual flexible hose.

The normal or "running" position is shown in **44**. A vacuum is maintained on the under side of the valve, A, and the top side of the diaphragm, B, the atmospheric pressure being free to act on the top side of the valve, A, and the under side of the diaphragm, B; but on account of an excess of pressure the valve, A, is held tight upon its seating.

When a rapid action of the brake is required, air is suddenly admitted to the train pipe and thus to the under side of the valve, A, then the pressure acting on the under side of the diaphragm, B, is sufficient to cause it to lift the valve, A, and allow air to pass full bore both to the brake cylinder and to the train pipe, as shown by **45**. Immediately the brake is "full on," the valve falls to its normal position by gravity.

To obtain a graduated application of the brake, air in moderate quantities is admitted to the train pipe, and the area of the passage around the peg, C, is proportioned so that it will allow the necessary amount of air to enter the brake cylinder, and so obtain a simultaneous action of the brake on every vehicle throughout the train.

Westinghouse Automatic Air Brake. Air pressure is the power employed for working the Westinghouse brake. Each locomotive carries its own air compressor, which is driven by the steam from the boiler of the engine, and compresses air to a pressure of about 80 or 85 lb. to the square inch, or, in the case of the quick-acting brake, to 90 or 95 lb. When the locomotive is coupled to the train, this compressed air, with which the main reservoir has been charged, is turned on to the main pipe running through hose coupling the whole length of the train, and thence through branch pipes leading to auxiliary reservoirs carried by each carriage. Thus, when the train is ready to start, the whole system of reservoirs and pipes is charged with an equal pressure of air, which is ready at any moment to act instan-



47. WESTINGHOUSE QUICK-ACTING BRAKE. PARTS APPLIED TO TENDERS AND CARRIAGES

taneously upon the brakes by means of a device known as *the triple valve*. The following advantages and principles of operation are secured by this method of employing compressed air: (1) The power is continuous throughout the whole length of the train, and can be applied to all vehicles either by the driver from the engine or by the guard from any part of the train. (2) The action is automatic, instantaneous, and simultaneous. It applies itself with full force to every vehicle should the train separate or should a rupture of a vital part of the apparatus occur. (3) The brakes are

applied by a *reduction* of air pressure, purposely or accidentally produced. (4) The brakes are released by an *increase* of air pressure, which can be produced by the driver only by means of the air compressor on the engine.

We shall now proceed to describe in detail the operation of the Westinghouse quick-acting brake, references being made to the accompanying figures showing sections of the various parts.

Parts Applied to Locomotives. Every engine is fitted with the following parts [45]:

The *steam air pump*, A, B, which compresses the air; its steam cock, P; and lubricator, O.

A *main reservoir*, C, for storing the air necessary for releasing the brakes and recharging the auxiliary reservoirs.

A *driver's brake valve*, D, which regulates the flow of air from the main reservoir into the brake pipe for charging the train and releasing the brakes, and from the brake pipe to the atmosphere for applying the brakes.

Parts Applied to Tenders, Carriages, and Vans. A *triple valve*, F, by means of which the instantaneous action is produced, in conjunction with a *reservoir*, G, in which is stored the compressed air for applying the brakes.

A *brake cylinder*, H, with pistons and rods connected to the *brake levers* and *blocks*.

A single line of pipe, E, called the *brake pipe*, extending the whole length of the train.

Each van has a valve or cock, T, connected to the brake pipe, and a gauge, S, to indicate the pressure of air. By opening his valve a guard can stop the train, even against the will of the driver, if necessary.

Operation of Brake. The pump [46] being started by opening the steam cock, P, and admitting steam to the cylinder, air is forced from the cylinder, B, into the main reservoir, C, which is connected to the driver's brake valve, D.

When a train is to be charged—the hose couplings between the carriages having been united and the engine connected to the train—the compressed air stored in the main reservoir, C, is turned into the brake valve over to the left. It then fills the brake pipe, and flows through the branch pipe on the engine and tender and each vehicle to the triple valve, F [47], thence by a groove, and past a piston into a reservoir, G, where it remains until the brake has to be applied. Uniform air pressure then exists throughout the train, except in the brake cylinders, H, the brakes being off; and the pressure per square inch is shown on the gauge, L, connected to the brake pipe.

So long as this pressure is maintained, the brakes are kept off, as the passage from each reservoir to its cylinder remains closed by the slide valve; but letting the air escape from the brake pipe causes the triple valve pistons and slide valves to move towards the left, and to uncover the passages to the cylinders. The air stored in the small reservoirs, G, then flows into the cylinders, H, and forces out the brake pistons and rods, thus applying the brakes. From the foregoing it will be seen that the driver can, by turning the handle of his brake valve, reduce the pressure in the brake pipe, and thus apply all the brakes.

Releasing the Brake. The brakes are taken off by reopening the passage from the main reservoir, through the driver's valve, and thus restoring the pressure in the brake pipe; this moves the triple valve pistons towards the right with their side valves, and places the cylinders, H, in communication with the atmosphere by means of the exhaust cavity in each of the valves; the air used in the cylinders is thus allowed to escape, and the brake pistons and rods are pushed back to their places by springs inside the cylinders.

The driver's valve, D, shown in the diagram [46] is of the improved construction, with equalising arrangement. A small reservoir, U, is coupled to the nipple on the left of this brake valve.

Emergency Stops. The description so far explains the ordinary use of the brake. In an emergency, when the shortest stop possible is required, the brake-valve handle should be thrown full over to the right, which movement lets out the air quickly from the train pipe. This sudden reduction of pressure makes the first triple piston and slide move the full stroke, with the effect that some of the air from the train pipe, together with the air from the reservoir, passes direct to the brake cylinder, H. The reduction thus made in the train pipe helps the next triple valve to start, and so on to the end of the train. This action is so rapid that the brake is actuated by the driver in 2½ seconds to the end of a train of 50 vehicles, not less than 1500 ft. long.

The release of the brakes is made as previously described. The triple valve-cock plug [47] and handle, Z, have three positions. When the handle is down, the triple will be in ordinary or quick action; when half-way, it is cut out; and when right up, in ordinary action only.

The ordinary Westinghouse brake, which works on the same principle but carries a simpler form of triple valve, is used where emergency short stops are not likely to be required. The high-speed brake is an improvement on the quick-acting brake, invented in order to graduate the high pressure between brake blocks and wheels, so that this shall be gradually reduced as the train slows down, thus preventing skidding and undue wearing of the wheels. It carries a reducing valve, which gradually reduces the pressure as the speed decreases.

Failures of the quick-acting automatic brake are invariably on the side of safety. Here is a typical incident. On one of the hot days in the summer of 1911 a Great Central train booked to run 20 miles from London before making its first stop suddenly came to a standstill. Nobody had applied the brake. It was found that one of the brake hoses was charred to such an extent that a hole was burned in it, and the result was an automatic application. But what had ignited the indiarubber? Investigation revealed that a pane of glass in the roof of Marylebone Station had acted as a burning-glass, and that the breeze set up by the motion of the train caused the charred hose to continue smouldering till it was burned through.

Evils of the Dual Brake System. The dual brake system is a fruitful source of inconvenience, increased dead-weight, and additional cost, and sometimes, indeed, of danger to the safe working of a train as well. Nearly every Anglo-Scottish express train has to be equipped with both the vacuum and air brakes, because the English companies concerned use the former, and the Scotch the latter. Further, most of the railways are compelled to have a number of passenger train vehicles, such as family saloons, horse-boxes, and carriage trucks, fitted with both systems of automatic brakes for the purpose of working through to "foreign" lines, while, again, companies which favour the vacuum brakes are bound to keep a number of engines fitted with Westinghouse apparatus, and vice versâ.

H. G. ARCHER

How Line and Half-tone Blocks are Made. Photo-lithography. Reproduction in Colours. Collotype and Photogravure.

PHOTO-ENGRAVING

THE term *photo-engraving* comprises all methods of reproduction for printing in which photography takes the part of the artist in the older and more costly processes, such as engraving on wood and steel, or drawing on stone. The various methods used for the production of newspapers, books, picture postcards, etc., can be classified as follows: (1) Line process; (2) half-tone process; (3) photo-lithography; (4) three-colour process; (5) collotype; (6) photogravure.

Making Line Blocks. The first of these is the most simple. It is used for the reproduction of pen and ink sketches, and such prints or drawings as contain only black and white, with no intermediate half-tones. The original print is put on a copying board in front of a camera, and a negative is made in the ordinary way [see PHOTOGRAPHY]. In making a line negative, it is necessary that the lines should be perfectly transparent, and the background as dense as possible. For this purpose, the old-fashioned collodion or wet plate process is recommended, as it gives crisper and sharper lines than dry plates do, owing to the thickness of the gelatin in the latter. Collodion is prepared by dissolving pyroxylin (guncotton) in a mixture of ether and alcohol, the proportion of which is governed by the weather (about 200 grammes of pyroxylin, 20 grammes of ether, and 20 grammes of alcohol). In summer, for instance, more ether will have to be used, as it evaporates very quickly. To this solution is added a quantity of iodide and bromide salts (about 70 grammes ammonium iodide, 25 grammes of cadmium bromide and about 20 grammes calcium chloride). The collodion thus prepared should be allowed to ripen for a few days. It can be obtained ready mixed.

Sensitising and Developing Collodion. A glass plate is then carefully cleaned by immersing in weak nitric acid, and polishing after drying with a chamois leather and a paste of prepared chalk and methylated spirit. The edges are coated with indiarubber dissolved in benzol, to prevent the film peeling off. The collodion is then poured on to the plate, drained off at one corner, and gently moved about to allow the ether and alcohol to evaporate [1]. Whilst still slightly moist, the plate is immersed in what is called the silver bath, a solution of nitrate of silver in water, to which a few grains of nitric acid and iodide of potash have been added. As this makes the collodion sensitive to light, it is essential that this operation should be carried on in the dark-room. The silver bath should also be kept covered.

The exposure is regulated by the nature of the original; thus, under-exposure will cause the lines to spread, whilst over-exposure will cover them up, so that it will be impossible to get a clear print of the negative. After exposure, the plate is developed with a protosulphate of iron solution in water, of which the following is a formula: 64 oz. water, 4 oz. iron sulphate, 4 oz. acetic acid, 1 oz. to 4 oz. alcohol. Methylated spirit has been added to make the developer flow over the plate, as the latter is rather greasy and repels water. Acetic acid is also contained in the developer; it clears the image and prevents scum forming on the surface. After washing, the plate is fixed with cyanide of potash or hyposulphite of soda.

Intensifying and Printing. To make the background denser, the negative is intensified by immersing it in perchloride of mercury solution, and blackening it afterwards with ammonia if the lines are delicate. If they are fairly coarse, a solution of equal parts of bromide of potash and sulphate of copper in water can be used, and after washing, nitrate of silver solution. This intensifier is more powerful than the previous one, and gives the operator a better chance of rectifying mistakes. A solution of iodine and iodide of potash is now poured over the plate, which is washed and then cleared with weak cyanide of potash. This is the time to remedy slight imperfections, either in the preparation of the plate, or in the exposure. The plate is then blackened with hyposulphite of ammonia or sulphide of sodium.

The negative taken in this way is printed on a metal plate which has been carefully cleaned with pumice powder. Before this is done, another point has to be considered. The print on the metal itself would be exactly like the original drawing, consequently a print off this plate would be reversed on the paper, like an image seen in a mirror. To avoid this, the film either has to be stripped off the glass plate, reversed, and put on to another glass [this is described under Collotype], or the picture has to be photographed in the first instance through a prism, or by means of a silver mirror, which can be attached to the camera in front of the lens at an angle of 45° to it. It may also here be added that, though daylight can be used in exposing the negatives, or printing on metal, electric light is used by all the photo-engraving houses, as it is less subject to variation.

Printing on the Block Plate. We now come back to the metal plate, which is sensitised by a solution of potassium or ammonium bichromate in water, to which white of egg has been added (1 egg to 5 oz. of water, 10 grammes potassium bichromate, and a few drops of liquid ammonia). The plate is fixed on to a whirler, coated twice, and dried over a gas stove [2]. It is then exposed behind the negative in a printing frame, just as a piece of silver paper would be in ordinary photography. A few minutes are sufficient to make the albumen and bichromate on the exposed parts insoluble in water. The plate is then rolled up with a stiff, fatty ink which has been thinned by means of a volatile oil, such as oil of lavender. After letting the oil evaporate, the metal is put into cold water, and the surface gently rubbed with cotton-wool. This takes off the unexposed bichromate and also the ink adhering to it, and only leaves the coating and ink on the exposed parts—that is, the lines of the picture. The plate is now dried and covered with powdered bitumen, which sticks to the greasy ink and is dusted off

the plain parts with a camel-hair brush. It is heated until the bitumen melts and forms a protection for the picture against acid.

Etching and Finishing the Line Block. The plate is now ready for etching, but before it is put into the acid trough, the margin, back, and large open spaces in the picture should be covered up with shellac dissolved in methylated spirit, so that no acid need be wasted in etching metal which can be cut away quickly enough by machinery afterwards. For etching, the plate is put into an earthenware trough containing weak nitric acid, and gently rocked. After a little while it is taken out, and the acid-resisting surface strengthened by means of soft litho ink, with which it is rolled up; a soft nap roller is best used for this purpose. The plate is then dusted in with dragon's blood or bitumen and carefully brushed in four directions.

Rinsing under the tap will remove any particles of dust on the plain zinc, leaving only those that have stuck to the soft ink. The latter spreads slightly over the edges in the subsequent heating over a gas stove, and thus prevents the acid underbiting the lines. Care should be taken not to overheat the plate, as it will make the ink run too much. This process is repeated until the plate is etched deep enough—that is to say, till the lines stand out sufficiently from the ground to print well on the letterpress machine. All ink is then washed off with hot potash or turpentine and the plate rolled up again, this time with a very stiff ink and a glazed roller. This is done to get rid of the shoulder which has formed in getting the depth. One or two of these finishing baths are generally sufficient if the plate has been etched well. When all the shoulder has disappeared, the plate is cleaned again, the shellac scraped off the back, and the block is ready to be mounted. For this purpose all metal forming the margin or open spaces in the picture itself is cut away either by a fret saw or a routing machine, and the plate is tacked on to a piece of oak or mahogany which is afterwards planed down to the exact height of type—that is, nearly $\frac{7}{8}$th of an inch. The block is now finished. Ground tints are laid on line blocks by mechanical means before etching to give shading to them [3].

Half-tone Blocks. The next process, called half-tone, is much more complicated. It is used for pictures which have no sharp and black-and-white outlines, but a variety of tones more or less gradually blended into one another, which cannot, therefore, be reproduced by line. As the machine will only print a level surface, it is necessary to produce a block the surface of which, whilst perfectly level, must be regulated so that light and shade are expressed by a kind of grain in relief, which is very close in the shadows, and opens up as it gets lighter in tone. The simplest way to produce such a grain is to photograph it at the same time as the picture. For this purpose there are on the market so-called *screens*, which are produced by ruling lines diagonally on glass plates, then filling these lines up with lampblack, and placing two such plates together, to form a net. When photographed a short distance behind this screen, the negative will show the picture itself, cut up all over by a net which varies in strength, according to the nature of the image. Thus, on the negative the darkest parts will show a strong transparent net with tiny solid dots in the centre. This net gets thinner as the tones go lighter, till in the highest lights only transparent dots will remain in a solid net. The fineness of the grain itself is varied according to the nature of the work. For poster work, for instance, the screen will contain about 25 lines to the inch; for newspaper advertising a 50 screen is commonly used; most of the SELF-EDUCATOR illustrations are printed from blocks with 120 lines to the inch, whilst for finest bookwork 400 can be used. A photograph of aerated-water syrup tanks is reproduced in **4** in four different screens.

Exposure Through the Screen. Great care has to be taken to give the plate exactly the right exposure to light. It is best to use square diaphragms, or others with extended corners, as these give a square dot in the tones, which etches better on the metal than a round dot. It is also advisable to flash a white card in front of the picture for a few seconds, to give more body to the dots in the dark parts. It is not advisable to have the latter too black, as too much detail is lost that way. The negative is then developed, fixed, and intensified, in the same manner as a line negative. After intensification, when the negative is cleared with weak cyanide of potash, a good photographer can even improve on the original, especially if it be dull and flat, by forcing the shadows a little, or by etching those parts of the negative which lack brilliancy. A good negative should contain fine pinpoint dots in the shadows, a square dot, with extended corners that join on to the next, in the middle tones, and fairly fine, transparent dots in the high lights. If no prism or mirror has been used, the plate is stripped and reversed in the same way as a line negative, and the surface can afterwards be protected by albumen, gum, or thin gelatin solution poured over it; then it is drained and dried.

Sensitising and Etching the Half-tone Plate. The sensitising solution for the metal plate consists of fish glue, ammonium bichromate, and water; sometimes ammonia or white of egg is added. (Formula: 1 oz. clarified fish glue, 2 oz. water, 30 gr. ammonium bichromate.) The copper or zinc is cleaned very carefully with pumice powder or charcoal, coated, and put on a whirler. It is then turned slowly over a covered gas flame till the coating is perfectly dry, and exposed behind the negative for a few minutes. Then it is taken out and put into cold water, which dissolves the fish glue and bichromate where not exposed to the light. To show more clearly what the result is like, the plate is put into a solution of some aniline dye, which shows up the picture. Under-exposure makes the film come off the metal, whilst over-exposure fills up the dots in the dark parts. If rightly exposed, the plate is rinsed and dried. After this it is held over a gas flame and "burnt in." The image will at first vanish altogether, but gradually reappear, till it has reached a rich reddish brown colour in the darker parts and a silvery bluish tone in the high lights. It is then cooled off, and is ready for etching. If a black line is wanted round the picture, it can now be drawn with thin litho ink.

For etching, the plate is shellacked at the back for protection. Copper plates are etched with perchloride of iron at about 40° Beaumé; zinc plates in a weak bath of nitric acid, with some pyroligneous acid and sal ammoniac added (Formula: 5 oz. water, 6 oz. nitric acid, 1 oz. sal ammoniac, 1 oz. pyroligneous acid), to counteract the action of salts formed by the lead, etc., always contained in commercial zinc. The plate is left in this bath till a sufficient depth is reached, and the darker parts begin to open up. It is then taken out and proved on a hand press. If it is found that some parts require more etching, those that have had sufficient are covered up with litho ink, and the process repeated until no more etching is necessary.

Any spot or faults are then engraved by hand, and the plate is ready for mounting, as described above.

Photo-lithography. Photo-lithography is really a part of the half-tone process. In the ordinary way a print from a half-tone block can be made on a special transfer paper with litho ink, and then transferred on to the stone It is, however, quicker and less costly to make a print direct from the line or half-tone negative. The half-tone negative made for this purpose must be stronger in contrast than the negative for half-tone process on metal, as no subsequent etching is possible on the stone. The line negative need not be altered. Neither must be reversed, as they are not printed on the stone direct, but on paper first, which reverses them on to the stone. The transfer paper, which has a gelatin or albumen surface, is immersed in a solution of bichromate of ammonia, and then dried. It is exposed behind the negative in the usual way, and then rolled up and developed exactly like a line plate. When dry it is ready for transferring to the stone.

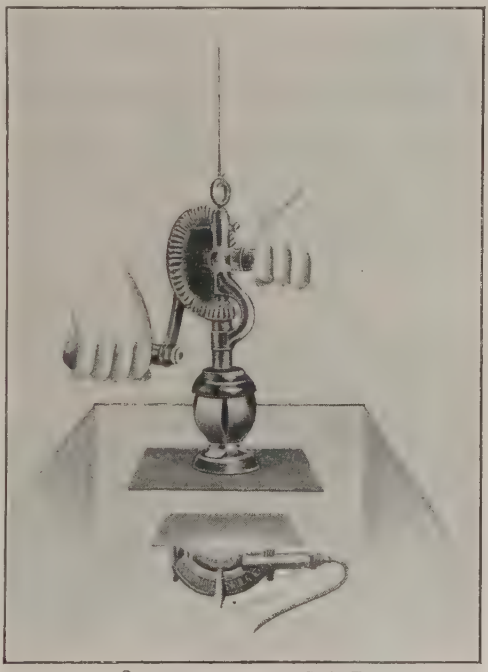
1. COLLODION COATING
Pneumatic negative holder

The Physical Basis of Three-colour Work. The next process, called three-colour work, is also a half-tone process, but, as the name indicates, has for its object reproduction in colours instead of in black and white only. Before going into the process itself, it will be necessary to explain a few things about light and colours in general [see PHYSICS, page 2587]. According to the now universally accepted theory, light is the vibration of the ether. A luminous body sends out waves of light in all directions, waves of different length striking the eye as differently coloured light. By being struck simultaneously by waves of different length, the retina receives the impression of white light, which is no single colour, but a mixture of colours. In the same way, if one series of rays be removed, the rest will strike us as one colour only.

All the spectral rays need not, however, be contained in the white light, as a suitable choice of two will give the same impression. These are called *complementary* colours—as, for instance, red and blue-green, orange and cyan-blue, etc. According to Young's theory there are only three kinds of nerve fibres in our eyes sensitive to light, and these communicate to us the primary sensations of red, green, and violet. These three colours are, therefore, called the fundamental colours. If all the three nerves are acted on simultaneously by light rays, we see white.

Pigments absorb colour rays. Now we must distinguish from light-emitting substances those which only reflect or absorb certain rays. Some absorb parts only, and reflect others, which combine together in a colour mixture, and thus give us the impression of colour. Substances, either in a solution or a powder, that absorb certain rays in a high degree are called pigments or dyes. To distinguish them it is necessary to keep in mind that a colour ray emits light, whilst a dyestuff only reflects borrowed rays.

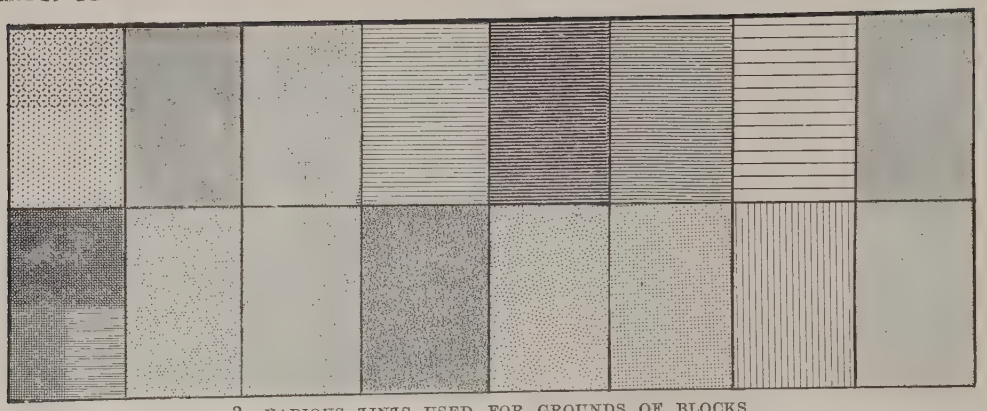
The Principles of the Process. For commercial purposes it is essential that a colour reproduction should be made with as few printings as possible to avoid expense; and it has been found that by mixing three pigments nearly all colours can be reproduced. These printing inks must be very pure and also fairly permanent if exposed to light. It will suffice here to say that the inks adopted are a yellow, red, and blue, which are a compromise between the various conditions



2. WHIRLER AND STOVE

The next thing is to produce negatives to correspond with these inks. They must show no action of light in those parts where the colour of the original corresponds with the ink, and the shades arrived at by blending this colour with the other two primary colours must be represented by gradations in the negative governed by this first colour. We must, therefore, exclude light rays of the particular colour which must be transparent in the negative, and only let those rays act on the plate which are absent in the reflected light of the pigment. Thus, for the red negative the plate must be sensitive to green, and equally for the yellow and blue negatives the plates must be sensitive to their respective complementary rays. To exclude light not wanted we have to employ so-called light filters. These consist of tanks from $\frac{3}{16}$ in. to $\frac{3}{8}$ in. wide, which are filled with aniline dyes in solution. The correctness of these dyes is tested with the spectrum. They have to correspond with the light-sensitive qualities of the plates used.

Dry and Emulsion Negatives. The negatives can be made with dry plates or emulsion.



3. VARIOUS TINTS USED FOR GROUNDS OF BLOCKS

For the former process there are various brands of plates on the market specially prepared for the purpose. For the emulsion process, any maker's emulsion, with the sensitisers sold with it, may be used. It may be added here that though the latter gives much better results, it requires great cleanliness, and cannot be worked in the same room or dark-slide and camera as the collodion process, because any free nitrate of silver has the effect of upsetting the emulsion.

The first negative to be made is the one for the yellow print. Any ordinary dry plate will do for this, as it is not sensitive to yellow, while the lack of red sensitiveness is partly compensated by the ultra-violet sensitive qualities of the plate. For this reason no filter is necessary to exclude yellow rays, the filter being merely filled with ordinary water to ensure register.

A set of dry filters can be procured at any house supplying materials for photo-engraving; but liquid filters are preferable, as they can be regulated very easily if they are not quite true. The best position for them is directly behind the lens. As they deflect light it is best to focus the original after they have been inserted. Plain emulsion, with a standard glycin developer (1½ minutes' development), or ordinary collodion, can also be used for the yellow plate.

The emulsion process corresponds with the wet-plate process in every detail, except that the silver bath is left out, the plate being sensitive to light without it. The coating has to be done in the dark, where the emulsion itself must also be kept. With one maker's emulsion, the method of working is as follows.

The Negatives for the Red Printing. For the second negative, for red printing, a plate is coated with emulsion, as before, but afterwards sensitised with sensitiser "A" (diluted 1 : 10), by floating it over the plate twice; or it can be mixed with the emulsion (1 : 10). For this purpose it is gradually added in small quantities, and shaken vigorously after each addition. Sensitised emulsion must be kept cool, and well shaken before coating. It must, however, be used up quickly, as it will not keep long, and increases in speed as it gets older. As the plate is very sensitive to light, only dark-red light may be used in the dark-room. Before developing, the plate must be well washed under the tap. The filter used is picric acid, about 1 : 1,000, or a corresponding dry filter. For gelatin plates, either orthochromatic or panchromatic plates can be used. Acid green and bichromate of potash solution serve as filter, or a dry filter can be used.

The Negative for the Blue. For the third negative, for blue printing, emulsion is used, mixed with "C" sensitiser in proportion 1 : 40. This is best worked in complete darkness, or with very dark green light. The plate must be washed before exposure. This emulsion will keep in the sensitised state. A mixture of 6 parts Biebrich's scarlet (1 : 1,000) and 10 parts aurantia (1 : 1,000), serves as filter. The same filter will do for red-sensitive or panchromatic dry plates. It is possible to get plates highly sensitive to colour by taking ordinary dry plates, and sensitising them with eosin, silver cyanine, etc.; but the beginner will have sufficient difficulties with ordinary plates or with emulsion without experimenting any further.

Another point which has to be taken into consideration is that if the angle of the half-tone screen is the same in each negative, a very peculiar effect will be given to the finished block, for the three grains will form what is called a Scotch plaid pattern. This difficulty is overcome by using two screens—one ruled at 45°, the other at 105°. For the third plate, the second screen is reversed, giving the angle of 30°. As the cost of screens is considerable, a circular screen has been constructed, which can be turned to any angle required, and thus the expense of a second screen is obviated.

The ratio of the exposure for the three plates is about 1 : 2 : 8, but varies considerably according to the original. The etching, etc., is exactly as in ordinary half-tone process, but, of course, after the first etch, a rough proof in three colours has to be made, to judge whether, and how much, further etching is necessary. With emulsion it is necessary to flash white card for the dark parts, as in half-tone process. This is not done with dry plates.

Collotype Reproduction. This is a purely photographic process, based on the fact that bichromated gelatin not only becomes insoluble when exposed to light, but also retains greasy ink which it otherwise repels. The grain necessary for the gradations of the tones is caused by the reticulation of the film itself.

In the first place a negative is procured either by dry plate or collodion process. If not taken through a prism or from a mirror, it must be reversed. This is very simple with collodion. The film is cut round, the negative put in water, and a piece of paper squeegeed on. The film comes off the glass easily, and is transferred to another sheet, and then back to a clean glass. Should the film be

too weak to stand this operation, it is first coated with a solution of Para rubber in benzol; then, after drying, with ordinary fairly thick collodion. Dry plates give more trouble to reverse, as the film does not come off the glass easily, and stretches considerably. To avoid this, the gelatin must be hardened with alum or formic acid. To make it leave the glass, it is soaked in a mixture of hydrofluoric, acetic, and citric acids, to which glycerin has been added. Instead of glass, the film can be reversed on to celluloid sheets, which, besides other advantages, are lighter, and take up less room,

Preparing the Collotype Negative. The negative is then marked off with strips of very thin tinfoil about an inch wide. This is best done on a retouching desk, where the picture is carefully squared up with pencil on the film side, and the tinfoil stuck on. The latter must be the very thinnest to ensure contact when printing. That the edges must be absolutely square and sharp is obvious. The negative itself must be full of detail and very soft.

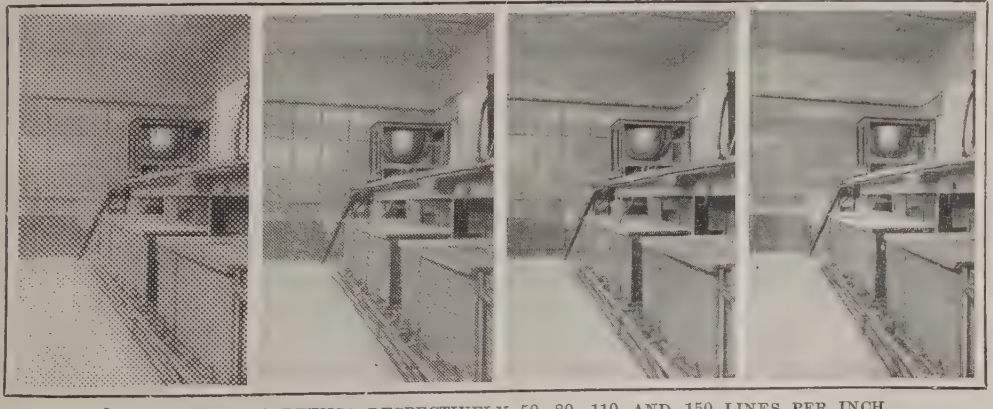
The next thing is to get a suitable support for the gelatin, from which the negative is to be printed on the machine. For this purpose, either glass or metal plates can be used. If glass is taken, one side of it must be carefully grained to give the film sufficient grip. This is done by putting emery paste between two glasses and moving them about gently till an even grain is arrived at. It should be neither too fine nor too coarse. The plate itself must be about ¼ in. thick, to avoid breakages, and the edges should be bevelled, as they might otherwise cut the inking rollers in the machine. Copper, zinc, or aluminium can also be used. Zinc is cleaned with emery powder and a brush, and then passed in a weak nitric acid and alum bath. (Formula: 60 minims nitric acid, 1 quart water, and 1 oz. alum.) Copper is ground like a glass plate, and aluminium is treated with weak sulphuric acid (1 : 31) or with a strong potash bath.

Glass, before being coated, has to have a substratum of albumen and potassium silicate. (Formula: 7½ parts albumen, 3¼ parts of potassium silicate, and 9 parts of water.) Instead of the albumen, stale beer may be used. The mixture is well beaten up and filtered, and after dusting the plate, is poured on, drained off, and dried. The plate is then washed to remove superfluous silicate, and dried again. Before coating, the plates are evenly heated to about 120°, great care being taken to prevent them from sweating. This is best done in a drying oven on a levelling tripod, where the plates are also dried after coating.

Coating the Plate. The solution consists of gelatin or isinglass, some bichromate salt, ammonia, chromic alum and water. The gelatin should be fairly hard, as this gives the plate a longer life on the machine, though it gives more trouble in etching. Both bichromate of potash and ammonia are used. The proportion of the two is ruled by the fact that the former is slower than the latter. A plate coated with the two gives more detail in the dark parts, and more definition than if one salt only is used. The proportion of the bichromate to the gelatin is defined by the salts crystallising out, if in excess. The proportion of gelatin to water is about 1:10, and a little chromic alum is added to avoid excessive relief. The gelatin is first swelled in cold water, and the salts used are dissolved in another vessel. The gelatin is then heated, but not more than from 120° F. to 140° F., and the salts are gradually poured in and stirred. The solution is then filtered through chamois leather, if possible by a filter pump. The solution must be kept warm during the filtering and coating. The plate is fixed on a tripod and warmed, as previously described, and the liquid poured on. It may be guided a little with a clean glass rod to spread it evenly over the plate, and the utmost precaution must be taken that no bubbles or particles of dust remain.

Drying and Exposing. After coating, the plate is dried at about 120°. This takes about two hours. During and after this time it must be kept in the dark, as, once exposed, the action of the light continues and spoils the plate. When dry, the plate should be perfectly even and matt. If glossy, it shows that the gelatin was too cold. Any vibration or cold draught during drying will be shown by wavy or streaky marks. The plate is exposed to light in frames, exactly as in half-tone process, and if several negatives have been stripped on to one plate, they can all be printed at the same time. All waste space between pictures has, of course, to be masked with tinfoil. For exposure, it is best to use an actinometer. If glass plates are used, an additional short exposure to the plate from the back is advisable, as this gives the film more hold on the glass and prevents excessive relief of the picture.

The plate is then washed in cold water, till all unexposed bichromate is removed. This takes about two hours. The subsequent drying also takes a few hours, but at least a day should be allowed to pass before the plate is put on the machine, to give the gelatin time to harden.



4. HALF-TONE SCREENS: RESPECTIVELY 50, 80, 110, AND 150 LINES PER INCH

The So-called "Etch." The plate is then put into a bath of water, glycerin, and salt, ammonia being sometimes used instead of the latter. The object is to make the plate absorb moisture. This is called an "etch" (though it is nothing of the kind). It is done to enable those parts which have been exposed least, and which, therefore, absorb more water, to retain the smallest quantity of fatty ink in the printing, whilst the fully exposed parts hardly absorb any water, and therefore retain nearly all the ink. After about half-an-hour, the plate is taken out and wiped with a sponge and dabbed with a clean rag to dry it. The ink used must be very stiff, only thinned down with a little varnish. It is rolled up very carefully with a nap roller till the plate, which will not take any ink at first, looks black all over. It is then rolled with a composition roller, which cleans it up, and is now put into the press. An albion, lithographic, or even a letter-copying press will do. It is best to put a few sheets of paper under the plate to prevent breaking, and to back the proof sheet with blotting paper. If on the proof the shadows are filled up, and the high lights are dirty, the plate is cleaned with turpentine, and re-etched. This is repeated several times until a satisfactory result is obtained.

Skies or dirty margins are cleaned up by etching the plate with a weak cyanide of potash, or a strong hypo solution, on a brush. If the plate is wanting in contrast, an etch is given without cleaning the ink off. For a short run, the plate margins can be masked with oiled paper instead of being etched with cyanide. When a proof shows a satisfactory result, the plate is ready to be put on the machine.

The Art of Photogravure. Photogravure is an intaglio process—that is to say, the surface of the plate does not represent the picture, as in all the other processes, but when the plate is inked in, the surface itself is wiped clean, and the picture is produced by the paper being pressed into the crevices to pick up the ink. The process of producing the plate is not complicated, but requires great skill in the final stages, and a good deal of artistic sense and judgment.

In the first place an ordinary negative is made from the original, and from this a transparency either on a dry plate by contact (and if another size is wanted, in the camera), or on a pigment paper. For the latter purpose, a so-called autogravure tissue is procured. Of the two kinds, it is better to procure the one not sensitive to light, as the other does not keep. Before use, it is sensitised in a bath of bichromate of potash and water with a little ammonia added, for about three minutes. A piece of plate glass is then carefully cleaned, rubbed over with French chalk, coated with plain collodion, and the tissue squeegeed on to it. This must be dried in the dark, for, when tissue is once exposed to light, the process of making the gelatin insoluble continues. The negative is then safe-edged—that is, all the edges of the picture are covered with strips of black paper or black varnish.

Another glass plate is then cleaned, coated with bichromated gelatin, and, after drying, exposed to light, to make the gelatin insoluble in hot water. This is to serve as support to the tissue during and after development. The tissue is then exposed to light behind the negative, and as this carbon process cannot be watched, an actinometer must be used with a piece of P.O.P. First the speed of the tissue (which varies according to the make) will have to be tested by comparing it with silver paper which is exposed simultaneously.

After exposure, the paper is put into cold water till it loses all tendency to curl. It is then squeegeed on to the gelatinised plate, and after standing for a few minutes, is developed in water at about 120° F. The backing paper will then come off easily. The water is now renewed, and the picture can be dried as soon as it has been well developed and all soluble matter removed. Under or over-exposed plates will be useless, as all the detail must be clearly defined both in the high lights and shadows.

The copper plate is now dusted in with finely powdered bitumen. This is done in a so-called "dusting box" containing a fan, which violently whirls up the dust. The copper plate, carefully cleaned with whiting and ammonia, is introduced in the centre on a large board, and the dust is allowed to settle. The longer the plate is left in the box, the finer and closer the grain will be. The time is from five to ten minutes. The plate is now heated, and the bitumen melted on. If the graining is not sufficient, the plate can be put back into the box again, and the process repeated.

Finishing and Etching the Plate. For the next stage, a special autogravure carbon tissue is prepared as the one before, except that the glass plate must not be collodionised. It is exposed behind the transparency, the latter having been safe-edged previously. After exposure, it is taken out, immersed in water, and rubbed gently with a sponge to let the water soak in evenly. The copper plate is also sponged and the tissue squeegeed on to it, and then weighted, after backing it with blotting paper. It is developed as before and is ready for etching, the margins having previously been dried and varnished.

The solution for etching consists of perchloride of iron in water, the perchloride having been neutralised with ferric oxide while hot. There should be five baths, varying in strength from 45° to 32° Beaumé. These baths can be used over and over again, as they improve with use. They will have to be tested occasionally for strength. The plate is first put into the weakest solution (45° Beaumé), where it remains till the copper under the shadows discolours (about one minute). The next two solutions, which attack the half-tones, take about one and a half minutes, while the final baths take from two to three minutes respectively. The plate should be etched one minute after the highest lights have been attacked. Finally the plate is cleaned with carbonate of soda, the film rubbed off, and the margins cleaned with benzol, and brightened up with weak caustic potash and very weak sulphuric acid. When the plate is quite finished, defects can be remedied by rouletting and burnishing. After this, the plate is steel-faced and is ready for proving.

Classes. Classes in the above processes are held at the Polytechnic, Regent Street, and the Bolt Court School of Engraving, Bolt Court, Fleet Street, London, as well as in similar institutes all over the country.

P. G. KONODY

Private and Political Secretaries. Parliamentary Agents. Lecturers. Institution Officials.

THE WORK OF THE SECRETARY

Secretaries. No particular technical training can be prescribed for the secretarial life. There is no one branch of knowledge in which the private secretary must excel, yet he should be in some sense acquainted with them all. The berth is pre-eminently one for a man of good general education and some knowledge of the world. It is one into which some men drift almost by accident, to remain there all their lives; others use it as a stepping-stone towards a more satisfactory position.

The Amanuensis. Broadly speaking, there are two classes of secretaries. The first is essentially a letter-writer, a very necessary adjunct to every wealthy man much occupied with affairs; the second—the political secretary—is an incidental luxury in literary and political life. The duties of a secretary of the first class are in many cases heavy, and the pay, except for rare and fortunate individuals, low. Such a secretary is, in fact, a clerk of more or less skill and responsibility; he has a clerk's duties, a clerk's position, and rather less prospect of promotion than most clerks enjoy.

Still, if a man can be satisfied, for a time at least, with an income of £100 to £150 a year, he may do worse than become a clerical private secretary to a person of influence and position. There is always a chance of impressing his chief with his ability and character, and so securing transfer to a more responsible post.

Qualifications and Position. The qualifications required by a secretary of this class are substantially those of a clerk in a City office. He must have some knowledge of typewriting and shorthand, a presentable appearance, and sufficient acquaintance with the English language to be able to write a good letter. Above all, he must be able to produce evidence of high character, and must show himself possessed of common sense and great discretion. His employer wishes to be relieved of responsibility in the smaller matters of everyday life; and a secretary who can be trusted to look after things intelligently on his own account becomes indispensable to a busy man, and can make his own terms.

On the other hand, a secretary of this class must be at the beck and call of his master. Not infrequently he lives in the house, and is hardly free from duties morning, noon, or night; no Factory Act applies to his employment, and no code defines his social position. Altogether it is a strenuous life, and a poorly paid one.

The Political Secretary. But the position of a secretary of the second class is very different, and far more satisfactory. His mission is mainly to serve as a well-informed companion and friend of his principal, who is often a business man unfamiliar with political and social interests. His employer's lack of knowledge is the political secretary's opportunity.

The salary of such a secretary is from £200 to £500 a year, and his social position is not so far off his chief's. Many Parliamentary private secretaries are less the servants of their immediate employers than apprentices to the game of politics, just as the editor's private secretary is an apprentice to journalism.

Posts of this class, however, are not so easily found as the ones before described. A luxury is expected to be a highly finished article. Generally, a Parliamentary secretary is an Oxford or Cambridge man, though some of the most successful ones have not been through the university. But, whatever his training, the qualifications of such a secretary are varied and peculiar.

Lord Brougham said once that the King knows as much law as his Chancellor, but the Chancellor knows where to find it. Even so the secretary—facts and figures, books and blotting-paper, he must know where to lay his finger on them all. Beyond this, unless he writes letters, which many do not, he holds something of a sinecure, and that not ill paid.

To the man contemplating a political career, no training could be more valuable than a year or two as private secretary to some prominent M.P. He meets many important people; he appears occasionally on his chief's platform, and learns to face an audience without quailing. When duties press heavily on the member, the secretary may be charged to make notes for a speech in the House, and so himself lend a hand with the helm of the vessel of State.

And the field is an open one. Some posts, of course, go through influence, but the central party agent can always find a berth for a man who impresses him favourably.

The Woman Secretary. There are many well-paid openings for women in the secretarial world. Authors, editors, and social and philanthropic workers, as well as men of business, find that a trained and tactful confidential secretary can lighten their shoulders of a great burden of work and worry; and many who would shrink from allowing a man to have access to their private papers and personal affairs have no hesitation in confiding these to the charge of a woman of the right type. For such duties a salary of £3 to £6 a week is not considered excessive.

The qualities needed for work of this kind include, in addition to those of the trained

typewriter-clerk, the wider outlook and surer judgment of a well-educated gentlewoman. The woman secretary requires especially the solidly based self-confidence that enables her to handle details without troubling her principal for directions. There are several secretarial bureaus that provide a useful course of training, extending over six or twelve months, at a cost of £20 to £50. But the woman who succeeds as a secretary does so primarily in virtue of personal qualities and force of character.

Political Agents. The same comment may be made on the profession of Parliamentary agent. Each of the two great political parties has an institution for training its agents in connection with its central association, and issues certificates to those who are qualified. But the really successful agent is he whose full energies and abilities can be thrown into the great game of politics because he finds the game absorbing for its own sake. To such a man the work offers a congenial career and the satisfaction of doing yeoman service to his party.

It has even been said that the personality of the agent is more important in a constituency than that of the candidate.

The Parliamentary agent usually begins as an assistant or sub-agent, thus gaining useful knowledge of election law and practice, which should be supplemented by the study of modern political history. It is a great advantage if he can speak readily and pointedly from the platform, but the first essentials are boundless energy, organising ability, and tact.

The Agent's Duties. Apart from election times, the political agent's chief concern is to "nurse" and safeguard his party's interests in the constituency. He must study local industrial conditions and the political questions most affecting the electorate. Much time and trouble must be devoted each year to the revision of the register of voters for the division, to ensure that all electors of the right political complexion appear upon it, and that all claims for registration issuing from the opposite camp are scrutinised for possible flaws. This involves some strenuous fighting before the Revising Barrister.

When an election is pending, the candidate appoints an election agent, who is usually the local Parliamentary officer. Then follows for the agent a whirl of multifarious activities, increasing in intensity until the day of the election itself. An election agent needs a strong constitution as well as political ardour to carry him through the strain of such a time.

Considering the demands made by this calling, its rewards are not high. Salaries range between £120 and £400 or £500 a year, £250 being about an average figure.

Lecturers. Apart from posts at the universities, which were discussed on page 5352, the calling of the lecturer is usually entered by one of two doorways. The first is open to almost anyone who attains distinction in some special and interesting department of knowledge, even though he or she has few natural gifts for lecturing, and had never contemplated it as a career. Whatever the subject—whether wireless telephony or mediæval music, the private life of the Kaiser or of the ant, Egyptian symbolism or germ-cells—the acknowledged expert is likely to be approached by some wide-awake lecture agency with a tempting offer of guaranteed fees. The European War, for instance, is now providing and will continue to furnish subjects for the lectures of a whole generation of experts, both military and historical.

The second class of lecturer belongs to the order of popular entertainers. Like the actor or singer, he begins without a ready-made reputation, and must win the suffrages of his public by his personal qualities and gifts. Of these the foremost essentials are a good delivery and pleasing voice, ready speech, a sense of humour, and that indefinable power of holding the attention of an audience which many men enjoy who are faulty orators. A degree is useful also as a proof of education and ability.

For the unknown man or woman, lecturing is usually an uphill calling, during the early years at least, and its remuneration is not comparable with that of the stage or even the concert-room. At first, engagements are few, even at a guinea an evening. As the lecturer's reputation grows, so do his fees, but many men of standing in the profession are glad to receive five guineas for a lecture. The surest way of earning a steady income is an engagement with a good lecture agency, which arranges full winter courses of lectures for its clients at an agreed fee. With a few outstanding exceptions, £10 10s. an evening is a high figure for the lecturer of this class. And late hours, night travel, and the nervous strain attending all public speaking make the life a trying one.

Institution Officials. The many posts for workers of either sex in charitable institutions, social missions, and learned and other societies are so various in their requirements as almost to defy any method of grouping. Most of them require some special knowledge of the conditions affecting their own particular activities. Thus, in charitable and social work, some experience of the wants and ways of the poor is generally essential, as well as the ordinary qualifications of a clerk or secretary.

The leading officials of a literary or learned society have usually served their informal apprenticeship in its office, and their intimate knowledge of the society's workings enable them to command salaries of from £300 to £800 a year. Charitable institutions are seldom able to pay adequate salaries, but the opportunities they offer of useful service attract to them many able men and women. The Charity Organisation Society employs a large staff of gentlewomen, who usually give their services for the first three months. They then receive £80 a year as assistants, and, if suitable, become local secretaries at £100 or £150. Matrons in industrial homes can have had no more useful training than that of probationer in a hospital, added to some knowledge of cookery or housework. Their salary ranges between £30 and £70, with board and residence.

Opticians. Painters and Decorators and Plumbers.
Photographers and Photographic Dealers. Saddlers.

ENCYCLOPAEDIA OF SHOPS—9

OPTICIANS

Qualifications. The man who intends handling an optician's business needs a certain amount of scientific and technical education. If he has had the advantage of being apprenticed to an optician, so much the better, but in any case he should take a course of lessons in technical and practical optics, such as those conducted by the Northampton Institute, Clerkenwell. Day and evening classes are arranged at moderate fees. Optical classes are also held at various centres in the provinces, and in London by private instructors.

Examinations are held by the British Optical Association and the Spectacle Makers' Company, and the diploma of one or both of these bodies should be secured. Full particulars as to the fees and subjects of the examinations may be obtained from the societies in question; and it is safe to say that the opticians who are able to pass both the elementary and advanced examinations have an excellent working knowledge of optics, which gives them considerable qualifications for their difficult and highly technical business.

The optician cannot, of course, expect to go into cases of disease affecting the eyes, nor should he attempt to do what is essentially the work of the oculist. But there is no reason why he should not become skilled in testing the eyes for the more common defects—such as, for instance, short sight and astigmatism.

Capital for an Optician. To start an optician's business independently of any other trade requires a capital of about £250, but, of course, if the business is to be only a department of a jeweller's or chemist's shop, then much less will do. Of the capital named, £20 may be spent in window fittings and outside signs, £40 in shop fittings, £100 in stock, £10 in testing-room fittings, £15 in testing appliances, £5 in workroom appliances, £10 in advertising, and £50 may be left for working capital.

Shop and Window Display. For an outside sign a large pair of gilt spectacle-frames are excellent, because, while being dignified, they tell the story at a glance. Such a sign will cost about £2; and enamelled spectacles may be affixed to the windows, these costing from 5s. to 10s. a pair. Fancy names for opticians' shops, like the Ophthalmic Institute, Sight-testing Parlour, Refraction Rooms, and so on, should be avoided, as they have about them a smack of quackery which makes the better class of customer suspicious.

For the windows the framed diplomas won by examination make excellent advertising; and models and coloured charts of the human eye, busts with faces wearing spectacles and eyeglasses, lumps of Brazilian crystal, and sight-testing designs all make popular attractions. Spectacles and eyeglasses, frameless and in all kinds of frames, should be prominently displayed on coloured velvet; and if a set showing the various stages of a pair of spectacles, from rough crystal to the finished article, can be obtained for window display, so much the better. Velvet stands for the display of folders and spectacles are also made, and should be obtained.

Shop Fittings and Stock. In the shop a number of dignified charts may be displayed, but care should be taken that these do not give a suggestion of cheapness or quackery. The counter should be covered by a glass case containing spectacles, lying on a velvet ground. A stereoscope standing on the counter, with a view ready in position, is an attraction.

The stock will include spectacles in gold, gold-filled, and steel frames, and also frameless; eyeglasses in the same varieties, astigmatic clips, blue and tinted glasses, monocles, rimless and framed, motor goggles, lorgnettes in tortoiseshell and celluloid, shooting-spectacles, pocket lenses, reading-glasses, eyeglass cords and chains, spectacle and eyeglass cases, including châtelaine cases, artificial eyes, eyeshades, eye-baths, lens cleaners, and one or two microscopes.

Sight-testing Room. For sight-testing a room 10 or 12 ft. by 15 or 16 ft. is necessary, and the walls should be distempered a dull leaden colour. No pictures should be on the walls to distract the customer's attention, but test charts should be hung at one end, and there should be a comfortable chair at the other end, 10 ft. from the chart, and raised on a platform. This raising of the chair is useful for seating the customer so that he may have his eyes level with the charts, and it also gives an air of importance to the testing-room.

Light is an important item in the testing-room. If the natural light is not very good it is necessary to have a good artificial light, shaded and so arranged that the illumination of the chart is even. At least £10 should be expended on the case of trial lenses, everything, of course, depending upon their accuracy. The case should stand on a table by the side of the testing-chair. Various sizes of reading type must also be available, together with a trial frame, optician's rules, face measures, and prescription book in which to record details of each customer's needs. A hand-mirror and a wall-mirror should not be omitted from the equipment, for the use of ladies whose hair may get disarranged.

Method of Testing. The method of testing is as follows: the customer is asked to be seated, and the optician then takes up his place behind the chair. He adjusts the trial frame on the customer's face, and while each eye is being tested separately an opaque disc is inserted to blind the other eye. The left eye is first covered, and the customer is asked to read what he can on the test chart with his right eye. If he cannot read all that he should, a + 0·50 lens is put in the trial frame. If this lens improves the vision the case is one of hyperopia, and the optician continues to substitute stronger lenses until one is found that gives perfect sight. If, however, the customer could not see so well when the first lens was used, then it is changed for a − 0·50 lens. If this assists, the case is one of myopia, and the range of these lenses is gone through till perfect vision results. The left eye is afterwards tested independently in the same way.

Where, however, the customer is unable to see plainly all the radiating lines of an astigmatic chart,

the ordinary spherical lenses must be replaced or reinforced by cylindrical lenses, which are rotated until all meridians of the chart are clearly seen. To go into all the tests for different defects is impossible here, but they are described in the standard text-books on the subject.

The Optician's Workshop. The optician's workshop will need an equipment including a bench, a lathe, a lens surface grinder, lens testers, optician's pliers, screw-drivers, soldering apparatus, tweezers, screw extractors, lens drills, and a grind-stone if much mechanical work is to be done, but it will be better for the beginner to get the wholesale opticians to undertake his repairs.

Profits. The optician's business should be a cash one, and on many of the things which he sells his profits should be 25 per cent. Much depends upon the class of customer that he gets, as much better prices can be obtained for the same goods in some districts than in others. Prescription work—the carrying out of the prescriptions of oculists—should be cultivated, as not only does it bring customers for the spectacles, but if they are satisfied they are likely to come to the same shop for all their repairs and renewals.

Scientific Instruments. Another side-line that goes well with an optician's business, and also with a jeweller's, is the supply of scientific instruments. Of course, in few districts is there any very large demand, but, as the profits are roughly from 25 to 33⅓ per cent., the trade is worth catering for. In the neighbourhood of technical institutes, science schools, and the like, the demand is greatest, especially in provincial cities. Scientific instruments and apparatus should include optical instruments and lenses, radiographic, meteorological, and mathematical apparatus.

Chemical apparatus, electrical apparatus, hydrometers, alcohol-meters, and all the other instruments of this class, theodolites, compasses, sextants, slide rules, measuring instruments, and many others, are all in a certain demand wherever students of engineering and chemistry congregate.

PAINTERS AND DECORATORS

Contrary to the usual run of shopkeeping, capital in the painter's and decorator's business is not wanted *chiefly* for goods in stock for sale, nor for material to be used on the work, but will be required to pay the wages of operatives while work is in progress. Wages in the painting trade average from 65 per cent. to 75 per cent. off the net cost of the work, which may not be returned for some months.

It has been said that a small business could be started on a capital of £60. That sum named would suffice only for the smallest possible business with barely such equipment as would serve the requirements of two or three workmen at most, without margin for extension of credit and ordinary risk on occasion, and without stocking any materials. For a concern capable of dealing independently with the average requirements of a moderate class business in the present day, it will be readily admitted that a sum of at least four times that named above, or, say, from £250 to £300, should be available.

Credit. A partial set-off against the credit to be given is that when a business is well established the manufacturers and merchants who supply the trade offer similar credit for materials used. It follows, therefore, that with moderate good fortune a business should adequately finance itself after, say, the first year, with reasonable progression.

A considerable part of preliminary outlay will be for painters' brushes, tools, and scaffolding, such as step-ladders, planks, long and short stave-ladders (for outside painters' work), handcarts, etc., none of which will be directly chargeable to any client's account, and can be recovered only by the charge of a proper percentage for indispensable wear and tear.

It must also be remembered that the master is responsible, under the Employers' Liability Act, for the safe condition of all scaffolding, and must be prepared to compensate any workman who may receive injury through defect therein. This is usually covered by insuring, and the premium paid must be charged to the account for maintenance of scaffolding.

Preliminary expenditure on materials may be limited to the needs of the workshop, as the modern custom of keeping little or no stock of paperhangings or other decorative fabrics, now mainly sold from the attractive pattern-books supplied by the merchants, leaves the investor free to apply that capital in other directions.

Showroom. A minor business such as that quoted at £60 may possibly be conducted without a showroom, but not so the moderately good-class business, with a progressive future.

The higher-class wall-papers are made up in large "stand" books that may be displayed in an upright position on the floor of the showroom. For convenience of carrying to clients' own addresses for selection to be made, some merchants supply also a smaller-sized pattern-book of the same contents, and this will rest on the showroom table among other similar-sized books containing patterns of the various grades of lower-class goods. It is the general custom for the merchants to mark on the back of each pattern the full retail price, from which a substantial discount of 33⅓ per cent. is allowed to the trade, no part of which should, in justice to the responsibilities of the business, be sacrificed to the client.

Both merchants and manufacturers supply the trade in this way, but the merchants will be found the most convenient to the beginner, as their selections are made annually from the various manufacturers' productions and arranged in harmonious "sets," thereby presenting great variety. Every pattern inserted in the books is kept in stock during the season—extending generally from September of one year to September of the following year—and sometimes a successful pattern may be carried forward from one season to another.

Showroom Fittings. The walls and ceiling of the showroom should be decorated with different materials in a variety of styles to show, say, three methods of treating a drawing-room, the same number of dining-room schemes, and a smaller number of schemes for other departments as space may allow, separating these into sections by the use of mouldings, that may be shown as samples of panel, picture, dado, or other mouldings used in similar positions occasionally by the decorator in the conduct of his business. These sectional examples should each be a display of good taste and careful workmanship, to inspire confidence in the customer as well as suggesting suitable modifications and colour harmonies, blending or contrasting, brilliant, medium, or subdued in tones, light and airy or deep and rich, as occasion may require.

Examples of painted woodwork should also be found in some variety in every showroom. These may take the form of doors, panelled on both sides, and hung upon posts between the sections of wall decoration so as to swing either way and display

suitable varieties of painting in harmony with the wall schemes. One side of a door may be finished in a variety of grained woods, such as oak, mahogany, walnut, pitch-pine, maple, etc., as the painted imitation of these is occasionally called for.

Fitments, such as a "cosy corner," where clients may sit while selecting their wall-papers, and an arched screen between showroom and office, from which artistic drapery may hang, and in which ornamental stained glass or leaded lights may be effectively displayed, should find room where possible, because it frequently comes within the decorator's province to recommend and supply such fitments to complete the decorations of a house. These are usually white enamelled with good effect. The screen need not be higher than seven or eight feet, allowing ventilation and light over the top. In front of this screen there may be brass rods, fixed several inches from the wood, over which sample rolls of wall-papers may be hung for display.

A long, low table with shelves underneath, for the display of smaller pattern-books, colour studies, etc., a few comfortable chairs, and the indispensable good carpet or linoleum on the floor, practically complete the up-to-date showroom.

Shop Window. It is generally to the advantage of a good class decorator's business to make but little display of goods in the window. A white enamelled screen dividing the window from the showroom may be made to support a simple pleated curtain of unobtrusive art shade as a background, and a linoleum of subdued contrasting colour on the stage flooring, with one stand pattern-book opened at a pleasing decorative scheme, showing perhaps a deep attractive frieze with harmonious filling, and maybe a yard or so of rich brocaded silk draped over one end of this, will, as a rule, impress the right people in the right direction for good-class business far more than a heterogeneous assortment of many samples. A pretty and always attractive addition to the window display is an ornamentally designed easel, upon which rests a picture or a small-scale drawing of an interior, drawing or dining room, billiard-room, hall, or other example of decorated work in colours, which may be obtained from the trade journals or from special artists if the decorator does not produce such drawings himself.

Wall-paper Stock. Where business prospects reasonably demand the keeping of a stock of wall-papers, this stock should generally be confined to the more ordinary kinds and lower qualities, in the sale of which there is less fastidiousness to contend with than in the higher-priced goods.

The manufacturers and merchants quote specially low prices for "stock" orders, in "bales" of stated quantities, as a minimum total. This compensates the decorator for special risks, and enables him, when his stock patterns are selected from the pattern-books, to net an extra profit, while losses upon remnants costing, say, from 2½d. to 6d. per roll of a dozen yards—of which the average room requires from seven to ten pieces—will never amount to a very large sum.

A moderate outlay on these goods, say, £30 or thereabouts, would be adequate for a start, and might be made to embrace 70 or 80 varieties in lots of 25 or 30 each, with a total of about 2000 rolls in all. These will be renewable as required during the current season, and renewals should always be compared for exactness of shades before placing into stock, and any variation should be kept apart from previous stock.

Enclosed shelves or "racks" will be required for convenient storage of these goods The carpenter's work for construction of such racks as usually made for the purpose may be set down at about 50s. per 1000 rolls it is intended to place in stock. Each division of square shelving should hold about 30 or 50 pieces for economical manipulation.

Sale-shop. In connection with a good-class business in large towns there is very little cash trade usually carried on over the counter in the form of sales of materials only, though when a stock of paperhangings is laid in it becomes a paying department in a district where there is a considerable section of the public accustomed to buy these goods, arranging elsewhere for fixing. This is especially the case in country market towns.

Ready-mixed Paints. A profitable addition to this department will be a stock of ready-mixed paints in lever-top tins of saleable sizes, such as 1 lb., 2 lb., 4 lb., and 7 lb. These are obtainable in various qualities from most paint manufacturers. A good quality sold at a fair price will be the most profitable in the long run, as the commoner qualities have poor covering power, and are apt to become viscid by remaining in stock.

Paints ground to a stiff paste in linseed oil, such as white lead, ochres, umbers, reds, blues, greens, etc., may be likewise saleable, and could be kept underneath the sales counter in small kegs, covered with a little water (renewed daily), and a small wooden spatula kept in each would serve to supply the required quantities. A horizontal scale or spring balance for weighing these will be required.

Oddments of Stock. Painters' oils and varnishes will form other items of probable sales in this department. These are sold by measure, usually by the gallon, half-gallon, quart, or pint. In varnishes the sales will generally be confined to three or four varieties, such as pale and hard oak varnishes, black japan, stains, etc. Makers supply these made up in small-sized sealed tins, for convenience of sale. Painters' oils and spirits are not put up in this form, and must be sold from bulk.

Painters' brushes, tools, and sundries are likewise saleable stock, and may generally be of cheaper qualities than used by the trade workmen, as those who buy for a mere temporary purpose can seldom be induced to pay the price of the quality necessary to the expert.

Glass-cutting may also be a profitable branch of the sales department, but would be best conducted in the workshop

Profits. It will not be found profitable to conduct this business on a margin of less than 33⅓ per cent. gross—that is, one-third of the selling price—to represent profit, which is the trade discount officially arranged by the merchants and manufacturers in pricing their pattern-books.

Workshop and Stores. The store and paint-shop may be together or separate; the workshop is better separate where space permits. They are usually situated in back premises, and should be convenient for delivery and despatch of heavy loads by horse vans, with, if possible, a good yard for storage of long ladders, planks, scaffolding, hand-carts, empty paint casks, etc., and a "lime-pit" for slaked "putty lime" (used in repairing plaster work prior to painting and paperhanging, and for lime washing); covered sheds are usually provided for these items. In the stores, shelving, in several tiers above a bench, fitted around the walls may contain all the dry colours—in tins or strong paper bags, as delivered, the more expensive coloured pigments ground in oil and turpentine, such as lakes, siennas, Vandyke

brown, drop black, and decorators' large tube-colours, also the stock of varnishes, enamels, and the like, while from hooks in the ceiling should be hung the reserve stock of empty paint-kettles.

Storing Stiff Paints. The heavy paints for ordinary use, ground to a paste with linseed oil, such as white lead, ochre, umber, reds, blacks, driers, etc., may be stored under the benches, where they are easily obtained as required by opening the kegs, keeping a little water on the top of the paste to prevent it drying, and with a trowel or strong wooden spatula in each. A good spring balance should find a place on the bench, so that every article taken out may be weighed and booked, together with the name of the client or job for which it is taken, the same care being taken to book all returns, with similar particulars, adding the dates in each case. Near the scale on the bench should be a small desk, on which is always to be found the "workshop day-book," specially reserved for the entries just named, from which the general bookkeeping of the business may from time to time be accurately made up. In the centre of the store a square table covered with baize should be reserved for glass-cutting, and in a safe corner racks provided for glass.

The workshop should be fitted with benches with one or two shelves above, and drawers beneath, occupying two sides of the room, preferably with north and west aspects, as it is desirable to avoid direct strong sunlight for paint mixing. Some pigments are of a more or less gritty powder, and occasional grinding of these calls for the provision of a paint-mill (small hand-power cone mill), usually screwed down on to the bench of the workshop, and also of a paint-slab, with a stone "muller" or hand-grinding stone upon it. A good slab is one of thick plate-glass, ground to a very level surface, and set in a bedding of cement or white lead putty, with its frame bevelled off, and screwed down to the bench. A granite cobble-stone cut into halves will make two good mullers or grinding stones.

Oil Storage. In a corner of the workshop or stores a place must be found for three oil-tanks, or a stillage on which the export barrels may be placed when received. The former is the best plan, as there is sometimes leakage and loss from keeping the oils and turpentines in the wooden barrels as supplied by the merchants, due to shrinkage of the wood. Each of these tanks may contain from 50 to 150 gallons of liquid, and is fitted with a tap near the bottom for drawing off the oils as required. One will contain raw linseed oil, another boiled oil, and another turpentine, all of which are indispensable to the mixing of various paints.

In another corner bins are required for the storage of whiting and plaster. These should be in the driest corner, and kept dry by being slightly raised from the ground.

A pickle cask, large enough to hold ten to twenty paint-pots and kettles, should find a place under one of the benches. In this a solution of strong soda or caustic soda should be kept, and dirty paint-pots be placed in it as returned from operative work. They may be removed the following day, and will easily be made fresh and clean by washing in clean water to be ready for further work.

Smudge Pots. Any old paint mixed and returned as surplus from work done should be carefully saved, and emptied into receptacles kept under another bench for the purpose. These receptacles are called *smudge pots*—one is reserved for white, another for pale colours, another for dark colours—and within a reasonable space of time the contents of these smudge pots may be used for ordinary work, or later form a good addition to red lead paint for priming new work.

On the shelves above the paint-benches will be kept small jars of all usual paint ingredients, to be handy for frequent use, also palette knives and cleaning rags, of which there should be ample quantity, to prevent wasteful and objectionable untidiness.

On one of the benches small articles such as notice-boards, door-plates, etc., may be painted and lettered, also any embossing or gilding on glass may be carried out, while the centre of the workshop may be reserved for pieces of furniture under process of painting, large signboards upon easels, for lettering, etc., and the two blank walls not yet dealt with may be boarded and reserved for sketching out plans of wall or ceiling decoration from time to time to facilitate the actual work when operations are begun.

In the drawers under the paint-benches may be kept the decorators' pencils, tube-colours, palettes, etc., also stencil patterns, gilders' materials, and other small items of value, or for occasional use.

In beginning business, so many articles are required that it is a matter of some difficulty to keep within small expenditure. But by first making sure of indispensable articles in minimum quantities, and by adding small quantities of the remaining requirements, any shortage or omissions can be made up as occasion may require.

Stock for Workshop and Stores. On these lines, the following list may be taken as a minimum stock to start a business where work for at least half a dozen men and one apprentice may be anticipated:

PLANT

8 long ladders, assorted sizes, from 10 ft. to 40 ft. length, 12 pair assorted step-ladders, 5 ft., 7 ft., and 9 ft.; 2 pair 9 ft., and 2 pair 11 ft., painters' trestles; 3 doz. scaffold planks (2 in.), assorted, 6 ft. to 15 ft. long; 2 paperhangers' folding tables and trestles; 2 hand-barrows, with steel springs.

WORKSHOP AND STORES FITTINGS

Carpenters' work; paint mill; muller and slab; 2 strong easels; gas or electric fittings; 3 oil-tanks; spring balance, and sundries.

STOCK OF PAINTS, OILS, VARNISHES, BRUSHES, etc.

Turpentine, 1 barrel (3 cwt.); raw linseed oil, 1 barrel (3 cwt.); boiled linseed oil, 1 barrel (3 cwt.); white lead, ground in oil, 5 cwt.; zinc white, ground in oil, 3 cwt.; patent driers, ground in oil, 1 cwt; Oxford ochre, ground in oil, 1 cwt; raw umber, burnt umber, Venetian red, Indian red, Brunswick greens (light, middle, and deep), and vegetable black, all ground in oil, of each, ½ cwt.; Prussian blue, raw sienna, burnt sienna, Vandyke brown, orange chrome, lemon chrome, ground in oil, of each, 7 lb.; drop black, ground in turpentine, 14 lb.

DRY COLOURS.

French ochres, Venetian red, raw umber, burnt umber, lime blue, of each ¼ cwt.; Indian red, lime greens, vermilionette, and ultramarine blue, of each, 7 lb.; vermilion (genuine), 7 lb; lemon chrome, orange chrome, middle chrome, of each, 7 lb.; dry white lead, dry red lead, of each, 14 lb.; 10 cwt. best Paris whiting.

VARNISHES AND ENAMELS

5 gal. (in 1 gal. tins) best copal oak varnish (for outside); 5 gal. (in 1 gal. tins) best copal oak varnish (for inside); 5 gal. (in 1 gal. tins) common oak varnish (hard); 1 gal. (in ½ gal. tins) decorators' carriage varnish; 1 gal. (in ½ gal. tins) extra pale maple varnish; 1 gal. (in ¼ gal. tins) ivory white enamel (slow setting); 1 gal. (in ¼ gal. tins) snow-white enamel (slow setting); 1 gal. (in ¼ gal. tins) black japan; 1 gal. (in ¼ gal. tins) Brunswick black; 1 gal. (in ¼ gal. tins) japanners' goldsize; 1 gal. (in ¼ gal. tins) terebine; 1 gal. (in ¼ gal. tins) patent knotting

WINDOW GLASS

One crate.

SUNDRIES

Putty (best), picked lump pumice-stone, of each, ¼ cwt.; pumice-stone powder, 14 lb.; glass paper, 1 ream, assorted sizes (Nos. 00, ½, and 1); powder size, ¼ cwt. (best quality); old oil goldsize, 1 lb.; gilders' cushions, knife and 3 tips; gold leaf, 5 books; transferred gold leaf, 5 books; filling-up composition, 14 lb.; paint remover (solvent), 14 lb.; spirit lamp for burning off old paint; paint strainers, 1 doz. (patent detachable gauze); brush holders, 1 doz. (patent suspenders); paint pots and kettles, 12 doz., assorted sizes; stencil pins, 2 doz.; steel graining combs, one set in case; 12 covering sheets (rough sheeting, 2½ yd. wide, cut into 5-yd. lengths); 6 palette knives, 3 putty knives, 3 stripping knives.

PAINTERS' BRUSHES

Ground brushes, size 4/0, 2 doz. (oval shape); English sash tools, sizes 2, 5, and 8, 1 doz. each (best); bevelled varnish brushes, size 3/0, best lily bristles, 1 doz.; bevelled varnish sash tools, size 5, best lily bristle, 1 doz.; distempering brushes, ½ doz. 2 knot, 8 ounce, best quality; stipplers, 2 only, size 8 in. by 6 in.; hog-hair fitches (flat and round), assorted sizes, 2 doz.; lining fitches, 1 doz. assorted, ¼ in., ½ in., and 1 in.; stencil tools, 1 doz., assorted ½ in. and 1 in.; graining mottlers, ½ doz., assorted; graining overgrainer, assorted; badger softener, size 3 in., best quality; dusting brushes, 1 doz.

The total cost of an outfit like this would be from £170 to £180.

Totalling up the above figures, and adding the cost of fitting out the showroom and offices, apart from stocking the (optional) sale-shop, it will be seen that the preliminary outlay necessary to the independent conduct of this business in a moderately good way amounts to a round sum of £200, or thereabouts, including £30 for the showroom and office decorating and furnishing, leaving a moderate balance of £100 in the bank out of the £300 recommended as starting capital with which to meet wages and other current working expenses, pending the receipt of cash returns.

Plumbing. In conjunction with the business of a painter and decorator may be run that of a plumber. Apprenticeships now last about five years, and where premiums are charged they vary between £5 and £50, wages starting at 2s. 6d. a week and rising in the last year of the apprenticeship to 20s. per week.

Technical Instruction. Instruction in plumbers' work may be had at technical schools and institutions throughout the kingdom, and the fees are merely nominal. Examinations are held annually at the schools where instruction is imparted, and certificate awards are made by the examiners of the City and Guilds of London Institute (Department of Technology), South Kensington. Students who are successful in the written examination receive a certificate in the "Principles of Plumbing." Those who pass in both the written and the practical sections are awarded a certificate for "Plumber's Work." Students are recommended to attend a two years' course of instruction before presenting themselves for the preliminary examination, and those who consider themselves competent may enter for the ordinary grade examination without having attempted the more elementary part..

The Plumber in Business. The business of a plumber is not one demanding a large capital, unless it be attempted on an ambitious scale, and with a large stock of material.

The jobbing trade, being the most remunerative, should be cultivated. The price got for labour represents a large profit upon its cost. The wages of workmen vary from 6d. per hour in some country districts to 11d. per hour in London, and their hours from 47 in London to 56½ in some country towns. The price charged for labour, even in towns on the lowest scale, is seldom less than 10d. an hour, and in London a charge of 1s. 6d. an hour is not uncommon. The profits on material are also good—from 33⅓ to 100 per cent. on cost prices—when the work is ordinary jobbing, so that the plumber with even only half a dozen men in his employ may make a very good thing out of his business.

Estimate Work. New work is seldom secured otherwise than by competitive tender, and in most districts such work is cut down in price until profits are bare or non-existent. The new man must take a hand in this game of "beggar-my-neighbour" if he would establish himself. He has the advantage that in his eagerness to make a business he will work hard himself, and exercise a stricter supervision than his competitor claiming earlier establishment. Thus, he may be able to make a profit when the firm in a larger way could not come out of the job with a profit. On the other hand, he may be under the disadvantage of not being familiar with the practice of the architect or clerk of works, who may put him to expense by the arbitrary enforcement of useless clauses in the specification.

A non-remunerative job may often be made to pay by the *extras*, and a knowledge of the habits of an architect in adhering to the details of his specification is worth having when tendering for work under his charge.

Allies of Plumbing Proper. The term *plumbing* has come to be wider in its scope than the mere working in lead and the house sanitary fittings which was the origin of the name. It is usually allied to gasfitting and hot-water fitting, and sometimes to the installation of hydraulic plant, to electricians' work, and to tinsmithing.

The Merchant Side of the Business. Development of the merchant side of the plumber's trade is usually wise, particularly since the trade in incandescent gas fittings began to assume its present large dimensions. The plumber who keeps no front shop neglects an important means of feeding the working department, and allows to go to others trade which he might easily have.

In such things as sanitary fittings, the best method of display is to have a showroom arranged with samples of the best style of lavatory basins, baths, and closets, with water supply connected up. These samples should meet the demands of modern ideas on the subject of sanitation. The sum of £50 plus the labour would pay for fitting up a very fine showroom, say, two baths—one of the shower type—three or four lavatory basins, a similar number of closets, and perhaps a footbath. A tiled floor, and walls of tiles, or of "Emdeca," will add to the expense, but may be worth it and will make a handsome sanitary showroom sure to attract custom. The tile fitting can be done in his slack hours by any workman sufficiently expert. From the roof should be suspended some samples of gas pendants, and brackets should be mounted on the walls. It is unnecessary to carry heavy stocks of sanitary and gas fittings.

Stock of cisterns, faucets, unions, and plumbers' brasswork must, of course, be held in a fully equipped plumber's business. In the sale-shop and windows the public should be shown the latest things in gas lighting. Excellent use is sometimes made of tiny models of sanitary fittings in the window. The competition of the gas companies—municipal or otherwise—may qualify the wisdom of stocking gasfittings upon a heavy scale, but gas mantles and other accessories of incandescent gas lighting can be sold freely in spite of all the competition of companies and corporations.

Buying. The plumber who keeps stock of plumbing materials can usually do better in his purchases than the mere "office" plumber. He is not tied to the merchant so much, and can draw many of his supplies from the manufacturers, thereby securing keener prices. The terms offered by both merchants and manufacturers differ. When the standing of the plumber is known to be good, he can usually get three months' credit, or should he pay monthly or at shorter date—always an advisable course when it is possible—he will secure better terms.

PHOTOGRAPHERS

To become a professional photographer a boy with the proper aspirations should be apprenticed to a good country business when he has reached the age of sixteen. In some cases a premium of £20 to £30 is asked; in others no premium is paid; and, again, small salaries are not unusual. The young beginner is taught printing, toning, developing, and mixing up solutions for a year or so, and is then introduced to the studio, where he helps in the operating, until he is competent to operate himself. Retouching is the last department taught. During these three years the young man should attend evening classes at the local science and art school.

Remuneration. The salaries paid in the business of a photographer are from 30s. to 45s. a week, the amount depending on the experience of the assistant and on his ability as an operator. Many women are engaged in certain departments of the photographer's business. and they are quite successful as reception-room attendants, retouchers, printers, and mounters. The salaries paid to women range from 15s. to 30s. a week, according to experience.

Starting in Business. Whether the photographer decides to buy an existing business or to start a fresh one is a question which circumstances must decide. A photographer who starts a new business can soon make a reputation if he delivers his work promptly. A beginner, however, has often to make his name chiefly by work outside his studio. He will need to cater for work by taking local views, but should make a point of always being in his studio at certain times of the day, or he will never be able to build up a home business. As soon as the business is large enough to support an experienced assistant, most of the difficulties outlined above disappear.

Capital Required. It is hardly possible to state an exact sum as necessary for one starting the business of a photographer. Many have started on £20 or £50, but to start in a fairly comprehensive manner needs from £200 to £300. A studio, for instance, may cost £50 to £100, and the camera from £10 to £30. In the following estimate, a medium class of business has been taken as a basis of calculation:

Portable studio	£60
Furniture and carpets	20
Backgrounds and accessories	20
Camera, lens, and stand	25
Dark-room fittings	10
Apparatus (printing frames, retouching desk, washer, trimmer, rolling press, etc.)	10
Mounts and stationery	10
Plates, paper, and chemicals	10
Miscellaneous (including advertising)	15
Working capital	20
	£200

Premises. The above estimate provides for a portable studio, but it may be that waiting-rooms and dark-room will also have to be provided. Usually these last-named are the ground-floor rooms of a house, and lead to the garden, where the studio is situated. Rents are higher in town, but a business is built up sooner than in the suburbs. Many town business premises are handicapped by having no shop window, the showcases in a doorway being a poor substitute. If possible, have a shop window at disposal. The floor of the shop or reception-room should be linoleum (self-colour), and the walls look nice if papered olive-green, with white paint. The rule should be to avoid a pronounced colour. The furniture must be in good taste if a good-class business is to be cultivated; care should be taken to have comfortable chairs. Adjoining the studio a dressing-room should be provided.

The Studio. The studio is the most important consideration. It must be disposed so that the light is received from the north, or preferably from a north-easterly direction. The length of the studio should be not less than 24 ft. and the width 12 ft., although it is better, if space permit, to make it 35 ft. long by 18 ft. wide. The pitch of the roof is usually 35 to 45 degrees, the height to ridge being about 14 ft.

As regards the studio camera equipment, an average specification would be a 12 × 10 set, to cost, complete, £25. The camera is fitted with a dark slide to take one 12 × 10, one 10 × 8, one 8½ × 6½, two boudoirs, two promenades, two cabinets, and two carte-de-visite pictures. A good portrait lens and massive stand is also included. Many photographers start studio work with an ordinary outdoor outfit, with rapid rectilinear lens, and purchase proper studio apparatus as means permit. The other contents of the studio will be three backgrounds—a reversible neutral-coloured background, and one outdoor and one indoor scene—a headrest, rugs, palms, and grasses, and a few pictures for the walls.

The heating of the studio is best managed by means of a "siphon" gas-stove or by hot-water radiators, and it is essential that the studio be comfortably warm in winter, or successful results cannot be expected.

A dark-room must also be fitted up as described later, but this does not need to be large.

Mounts. The tints of mounts are numerous, but two kinds of mounts are well defined—Bristol and enamelled board. It costs about 5s. per thousand to have the photographer's name stamped on back and front of mounts, the price depending upon whether gold or colour is used.

These should be supplemented by a selection of circles and ovals, slip-in mounts, and mounts with greetings embossed upon them.

Tissue-paper covers for photographs, protector bags, and postal wrappers will be needed, as well as memorandum forms and billheads.

A registration system for negatives must be inaugurated, a ruled book being provided in which the name and address of each sitter is entered, with date and other particulars. The stock of negatives ought to be stored in a dry place, and be kept in order, so that there will be no difficulty in finding a particular negative.

Selling Prices. These vary according to the class of trade. The following are average prices: midgets, 4s. 6d. to 6s. dozen silver prints, 7s. 6d. platino; carte-de-visite, 7s. to 8s. 6d. dozen silver prints, 10s. 6d. to 12s. platino; cabinet, 15s. to 24s. dozen; boudoir, 18s. to 20s. dozen to 35s. dozen; panels, 10s. 6d. to 15s. each; wedding groups, whole plate, one to two guineas, including three to six copies.

Copyright. In the case of ordinary photographs the copyright belongs to the person who pays for the sitting, unless it is expressly reserved by the photographer. A book of forms should be provided for the latter purpose if the extent of the business allows it. The wording of the form is usually something like this:

"In consideration of your allowing me a reduction from your usual terms for taking photographs of me or on my behalf this day, I hereby agree that the copyright in such photographs shall be reserved to you, and that I will not deal in any way with the photographs to prejudice your interest in the copyright."

The reduction should be stated, and the agreement stamped with a sixpenny stamp, dated, filled in with the names of the parties, and witnessed.

Class of Work. Photographer's work is very varied. It includes copying old photographs, enlarging pictures by bromide, carbon, or platinum processes, architectural work, photographic enamels, flashlight groups of dinners, lantern slides, transparencies, picture postcards, and photographs for the Press.

A side-line neglected by professional photographers is the supply of plates, papers, and apparatus to amateurs.

Advertising. Advertising is much neglected by photographers. If more price-lists were distributed, more people would be led to have their pictures taken. Make a special offer of a certain style of photograph or enlargement, but in so doing do not make a mistake of cutting prices; rather make the quality and style better than charge a cheap-jack price. When sending home proofs, enclose a price-list of various styles in which the photographs can be printed, even though the customer has paid for the sitting. In many cases a few additional prints are ordered because some variation in style is fancied

Photographers' Profits. The photographer pure and simple should obtain a gross profit of 50 per cent. on the turnover. A source of much loss with many photographers is the waste of material that goes on. Spoilt plates and paper, and wasted solutions, especially if the last-named contain the precious metals, account for a respectable leakage in profits. The leakage can be stopped by proper supervision and systematic working.

Photographic Materials. Although usually run by chemists, the supply of photographic materials may easily be undertaken by any photographer who has a shop window. There is no apprenticeship in the business, the embryo dealer starts as a junior assistant, and works his way up. Wages are not on a liberal scale; 30s. to 45s. a week are fair averages for junior and senior assistants of experience; and it is not astonishing that any young man of enterprise and small capital soon looks about for a neighbourhood where he can set up in business for himself.

The best neighbourhood is obviously the busy residential suburbs of great towns or seaside resorts. Near public schools a photographic dealer can generally make a living, as successive generations of schoolboys take up the fascinating art.

The Dark-room. In connection with a photographic dealer's business, provision should be made for a dark-room for the use of amateurs. The room should be lighted by sliding shutters on the window, and the source of light for the ruby lamp should be gas or electric light. Means must be adopted for obtaining white light at will, as some printing processes require a white light for a few seconds at a time. A by-pass is a useful addition to the gas burner, but with electric light a separate lamp for white light is readily fitted alongside the ruby lamp. The walls should be painted a dull lead colour, the same treatment being applied to the ceiling. Water should be laid on, and beneath the tap should be a porcelain or lead-lined sink. The tap to the water-pipe should be fitted with a reducing nozzle, and a rose cap is an advantage.

The developing space should be on one side of the sink, and arranged so that splashes of developer and water drain away to the sink. Shelves underneath the sink and the developing bench should be fitted up for the dishes, while on the walls shelves are placed for the developing solutions and measures. Another table should be provided for the dark-slides while filling them or while the plates they have contained are being developed. This table should be arranged at the opposite side of the room from the sink, so that it is not likely to get splashed.

The room should be well ventilated. Any carpenter will understand when it is explained to him that he must make the ventilators light-traps. The inside of the door also must be trapped round the edges, but this may be rendered unnecessary by the provision of a curtain on the outside. The door should lock on the inside, so as to prevent the possibility of disturbance at critical periods of plate changing or developing. A refinement in dark-room doors is to have two doors separated by a lobby, so that a person can enter the room without admitting light. To casual customers a small charge —minimum, 6d.—is made for the use of the dark-room for plate changing, but if the customer be also a purchaser of goods at the shop it is unwise to press the charge. When the room is used for developing plates a charge of 1s. is made, this amount covering the use of the room for an hour.

Capital Required. The amount of capital required for starting the business of a photographic dealer depends upon whether it is to be subsidiary to another business or to be mainly photographic requisites. When started in connection with a photographer's or drug business, a ten-pound note would suffice to stock the most frequently required apparatus and plates, the chemicals being already articles of stock. Great care must be taken not to lay in a stock of plates and papers that will last beyond the season, as these goods do not keep well.

When a new business is being started, the amount of capital will depend, in a measure, on the neighbourhood, but £100 is a medium figure. For this an excellent assortment of cameras, lenses, shutters, stands, view-finders, handbooks, dishes, racks, tanks, plates, ruby lamps, mounts, negative boxes, chemicals, trimmers, scales, bottles, papers, etc., can be secured.

Side-lines. It is becoming increasingly popular for amateurs to hand over their exposed plates or films to the photographic dealer for development and subsequent printing. Some amateurs do their own development, and hand the negatives over for printing. The profits are from 20 to 25 per cent. on this class of work.

Repairs to cameras and apparatus should be undertaken, and arrangements made with a manufacturer for promptness in carrying out this work.

The hire of cameras is another branch of the dealer's business. A few good cameras accumulate through being shop-soiled, or possibly by exchange with a customer requiring a new instrument. The cameras should be in perfect order, and if the

customer is unknown a deposit up to the value of the apparatus should be insisted upon. The charge for apparatus is 5 per cent. of the value of the camera per week, with a minimum of 5s. The charge for the hire of a camera for a single day should depend on the class of apparatus, but a minimum should always be fixed, as the convenience of hiring is one for which a customer should expect to pay.

Lantern slides are let out on hire at many large photographic dealers', the charge for the hire of a set of slides being from 1s. to 2s. per night, the customer paying carriage.

Picture framing is suitable for this business, as photographic enlargements are generally incomplete without a frame.

Profits. The profits in the photographic dealer's business, as distinct from that of the mere photographer, are good, but this should be qualified by the statement that much soiled stock is likely to accumulate if business is not brisk. The sale of such stock is, perforce, done at reduced rates, and, consequently, is profitless in some senses. On apparatus and accessories 33⅓ per cent. profit is allowed, varying with the kind of goods, but some proprietary articles allow a profit of only 10 to 15 per cent.

SADDLERS

The trade of a saddler and harness-maker seems to have fallen on evil days. The automobile is ousting the horse from the high-roads, and one of the attendant results is the lessened occasion for purchasing saddlery and harness by those who were wont to be the most liberal in their disbursements upon such articles.

Apprenticeship is general and necessary. The term of service was formerly seven years but it has become shorter in recent decades, and five years may now be regarded as the most usual term. The period is none too long, as there are a great many practical details to be learned, and the youth who has just completed his apprenticeship is never a thoroughly qualified craftsman. He must gain further experience for at least three years—preferably in a shop other than that in which his apprenticeship was passed—before he can claim thorough competence.

Sometimes a premium is required by the employer, but this is now rare, as the condition of the trade makes it difficult for employers to obtain apprentices even without the premium. Apprentices' wages vary. In many country districts they begin at only 2s. a week, rising to 9s. during the last year, but in London the wages during the first year are usually 5s. a week.

Journeymen Saddlers. The wages of journeymen saddlers are from 20s. to 40s. per week, and 30s. is about the average. The journeyman saddler frequently has no opportunity to learn the commercial side of the business, his time being spent exclusively, or almost exclusively, at the bench, but he should endeavour to obtain some commercial knowledge, say, as the manager of a branch business, or as assistant to attend customers or to buy goods and materials.

The Departments. The departments, if we may call them so, of the saddlery and harness business are three—the manufacturing, the selling, and the repairing. The saddler need never be idle. If his attention is not required by a customer, he may be doing repair work; and if neither selling nor repairing be possible at the moment, he may be making something for stock.

Capital. Many saddlers start in a small way of business, with a capital of not more than £100. With only this amount at disposal the selling stock must be small, as the greater part of the sum must be spent in working material, which is expensive. To open a medium-class business, the sum of at least £250 is required, and we may take this as a typical case for consideration. With such a sum financial pressure will be felt in intensity as the volume of business is great, because credit prevails to such a large extent, and the saddler can seldom receive payments as promptly as he has to make them. The premises required must be commodious, but need not be in the principal thoroughfares if rents are too high, as the orders are usually given by coachmen and grooms, and not by their masters. The shop-fittings are not elaborate or expensive—a strong, solid bench at which to work, a counter upon which to cut out and from which to serve customers; a few glass wall-cases for the better-class stock, such as bits, spurs, stirrup-irons, whips, and brushes; plenty of hooks and brackets from which to suspend harness, a dummy horse, a rail to show saddles, a supply of wooden shelves placed at different heights, and a small desk. All these, with the necessary working tools, would absorb, say £50 of the capital. The rest of the money, or the greater portion of it, would be spent upon the raw materials of the craft and upon stock, such as whips, horse-rugs, sponges, low-priced collars, and saddles, and proprietary articles, such as embrocation and harness composition, etc.

Full details of the methods of manufacture are given under Saddlery and Harness-making on page 4223 and the following pages.

Sundries. The list of saddlers' sundries is numerous. It comprises:

Brushes of all sorts, body brushes, whisk dandy brushes, whalebone dandy brushes, bass ditto, water brushes, spoke brushes (with and without handles), mane brushes, harness and boot brushes, breeches brushes, compo and carriage cushion brushes, cloth brushes, carriage washing brushes, oil and hoof brushes, dog and stable brushes, horse toppings, gig lamps, sponges, chamois leathers, creams, revivers, burnishers, and glove brushes; nose-bags, halters and halter reins, stable fittings; horse clippers, singeing lamps, scrapers, curry combs, mane combs, stable baskets, buckets, coaching baskets, etc.; corn servers and measures, whips, hunting crops, whip sockets, thongs, whipcord, etc.; body belts, girths, singlets, rugs, horse nets, bandages and rubbers, horse boots, knee-caps, body rollers, horses' bonnets, etc. Blackings, dubbins, polishes, cleaning pastes, embrocation oils, soaps, etc. Unfortunately, the last-mentioned articles are usually sold at cut prices by the stores and grocers. The saddler must protect himself by buying in the best market and making up his own blackings, dyes, etc., and by pushing their sale.

Side-lines. Leggings and gaiters are very profitable, and dog collars, leads, chains, baskets, and clothing are very saleable, if a little less remunerative. Bags and portmanteaus are intimately allied to the trade, and should by all means be put into stock. Driving-gloves are articles of frequent demand, and yield good profits. Saddler-made purses have a reputation for long life which they deserve, and are not to be despised.

Credit and Profits. As already mentioned, the business is chiefly of the credit order, and yearly and half-yearly accounts are the rule. The trading, both on the sales of articles bought and on the manufactured work, should show a gross profit of about 33⅓ per cent. on the return. Repair work ought to be more remunerative, chiefly for the reason that the proportion of material used is generally small, and the price is made up of labour, which should always carry a larger profit than merchandise.

The Tools and Materials Used by Painters, Paperhangers, and Glaziers. The Methods of Executing Various Kinds of Work.

PAPERING, PAINTING, AND GLAZING

PAPERHANGING

THE work of the paperhanger consists in preparing the surfaces of walls and ceilings, trimming and preparing paper of various kinds and other hangings with which in these days walls are frequently ornamented and in some cases protected.

Paperhangers' Tools. The tools used by the paperhanger are not very numerous. One may include with them overalls, which are generally made of "duck" or "drilling," which are always worn by the paperhanger and which are formed with pockets for rule and shears and a wide pocket across the front. *Shears* [18] are required for trimming papers before hanging; long ones are from 14 in. to 16 in. long, but shorter ones are also required. A *trimming knife* [19] is required of thoroughly well tempered steel; this has a deep blade with a rounded cutting edge, and is made in one or two different forms. It is used against a straightedge when trimming. A *cutting wheel* [20] is often used. This is really a circular knife with a thin, fine edge, which may readily be kept in a sharp condition. A variation of this knife, known as the *twentieth century cutter* [21], is provided with a ratchet. When the wheel is drawn forward it becomes locked, and a definite portion of the circumference acts as the cutting edge; by pressing the wheel backward it rotates slightly, another cog of the ratchet becomes locked and a fresh part of the circumference comes into play, so that a keen edge may be in use until the whole circumference has been brought into play, when it must be re-sharpened. These cutters may be used for trimming paper either dry or pasted.

There are various machines for trimming paper in long lengths before it is pasted, and these are made to trim one or both edges at once for any paper up to 22 in. wide. The *Empire trimmer*, made by Mr. J. Oates, of Huddersfield, has a rod in front of the machine on which the roll to be cut is placed, and a second roll at the back on which it is wound after cutting. The position of the cutting wheels can be adjusted to the exact width required.

Trimming Wallpapers. Great care is required in handling rolls of paper that have been trimmed mechanically; this is usually done at the shop, and if the rolls are afterwards taken to the job and made to stand on their ends, the carefully-trimmed edges will be damaged. Ordinarily, trimming is done on the job just before hanging, and all such damaged edges are removed by trimming; this operation is carried out on a trimming table erected on a pair of light trestles.

The *smoothing brush* [22] is a broad brush from 10 in. to 14 in. wide with a wooden back grooved to allow of its being held readily; these brushes are generally made of white Russian bristles.

Seam rollers are used for smoothing joints and are made of rosewood or ivory or of rubber [24], or they may be finished with a layer of felt, covered with muslin, which may be readily renewed when soiled. The width of the roller is from 1¼ in. to 2 in., and the surface is either cylindrical or barrel-shaped. In order to get close up to the work round the edges of architraves to doors and windows, and in similar positions, a *side arm roller* [25] is employed.

Smoothing rollers [23] are usually about 8 in. wide and are used for running over the general surface of work. They are sometimes made of polished hardwood mounted in nickel-plated frames; but in many cases these are also finished with a layer of felt, which is covered with muslin held in position by rings at each end.

The *brushes* [26] used by the paperhanger are made of long grey bristles mounted in wood handles so that they form a flat kind of brush from 6 in. to 8 in. wide.

A *size kettle* [27] is best provided with a water-jacket to prevent any possibility of the size being burnt when heated.

The paperhanger requires to use a plummet, a chalk line, a 2-ft. rule, a pail for paste, sandpaper, a tape measure, and compasses, and, very usually, cloths for smoothing down the paper in place of the smoothing brush already described.

Wallpapers. *Wallpapers* are made by various processes and are sold by the piece. In the case of English paper the piece is 12 yd. long nominal, and the paper is about 22 in. wide as sold, and 21 in. when trimmed for hanging, and has a superficial area of 63 sq. ft. French papers vary somewhat in length, but are usually 9 yd. long and 18 in. wide, and contain 40½ sq. ft. American papers are 8 yd. long and 18 in. wide, and contain 36 sq. ft. The pattern of a paper must therefore be made to repeat once or oftener exactly in the width of the roll. Borders and friezes are usually sold by the yard.

Papers that are printed are either machine printed or hand printed. The best results are obtained by hand printing, which is done from wood blocks; these papers may be known by the presence of a white margin at each end of the roll, as well as at each edge; this results from printing each piece separately, whereas machine-printed papers are printed in immensely long rolls and afterwards cut up into lengths, so that the pattern runs out to the very end. The colours in machine-printed papers are not always so well set as in the case of those printed by hand.

Pulp papers are the commonest class of papers; in these the paper itself may be a tinted paper and the pattern printed in colour, or in better papers both the ground and the pattern are printed.

Satin papers have a glazed or polished surface, giving an effect like satin; this is produced by mixing Spanish white with the colour and then thoroughly burnishing the surface. This class of paper is somewhat susceptible to damp, and it is often desirable to line the walls with lining paper before hanging it; but these papers usually keep a clean surface, as dirt does not readily adhere to them.

Flock papers have the patterns printed on a ground with an adhesive substance, and upon this shearings of wool or silk, very finely divided, are sprinkled, and these adhere, forming a raised pattern; the

wool flock gives a somewhat cloth-like or velvety appearance; the silk a somewhat glistening effect, and striped silk flocks are a good deal used.

Sanitary papers are printed from copper rollers in oil colour mixed with a strong adhesive material; such papers, when hung, may be washed, which is not possible with ordinary papers.

Ingrain papers, which are not printed, but coloured in the manufacture, are prepared in various tints, with a slightly mottled surface, and are rather soft and porous; papers are also made to imitate tapestry and other textile fabrics.

Special Wall Coverings. There are many other forms of wall hanging now in use, which are of a more substantial and permanent character than the ordinary wallpaper. They are, as a rule, considerably more expensive in the first instance, and require special treatment in hanging. Some of them are supplied decorated ready for hanging, others can be obtained perfectly plain for decorative treatment after fixing.

Japanese leather papers are thick in substance, usually slightly embossed, and decorated in colours with which a good deal of metal bronzing or gilding is included; these papers are usually supplied in rolls 36 in. wide and 12 yd. long, and in the majority the design is rather large in character.

Lincrusta Walton is a material generally modelled solidly in relief, and is produced in a great variety of designs suitable for dados, wall surfaces, friezes and also for ceilings. It forms an excellent base for colour decoration, and some of the designs in high relief may be treated plainly in one colour, a good effect being obtained by the contrast of light and shade without any picking out. *Cordelova* and *cameoid* are other forms of material manufactured and supplied by the same firm, and are also made in both low and high relief; in the latter form, when used for ceilings, they may be arranged to give the effect of plaster panelled ceilings.

Lignomur is another material with the design formed in relief. It is manufactured of wood fibre, and is embossed in hollow relief; it may be applied to walls or ceilings, and afterwards decorated in a variety of ways, either in oil colour or distemper, or it may be stained and varnished, as if it were a natural wood.

Anaglypta is also moulded in relief, both high and low, and is made by pressing pulp or plastic paper into moulds.

Tynecastle canvas is very extensively employed, and is also modelled in hollow relief, canvas being employed as the basis of this material; very bold relief is possible, and the material lends itself to decoration in colour after hanging.

Woven Wall Coverings. Woven and embroidered fabrics, used as hangings or mounted on frames, have long been used for covering walls, and come rather under the upholsterer's department than the paperhanger's. The drawbacks to such materials—their liability to become soiled, the difficulty in changing them, and the extent to which they may harbour dirt, and even vermin—have been serious drawbacks to their admirable qualities from the decorative and artistic points of view. In recent times, some of these materials, the texture of which is admirable, have been prepared so that they may be applied to the wall by the paperhanger practically in the same way as a wallpaper. To render this possible, the space between the fibres must be filled, and especially the back, so that it may adhere solidly to the wall, and not allow the paste to work through to the surface; the material itself must be dyed and fixed so that it will not readily fade.

Burlap, made from jute, is extensively used for this class of work; the fibre is lustrous, and the material strong and not very expensive, and admits of the surface being treated in colours, which may be either printed or stencilled on it. The material can also be obtained in very wide widths, so that it is possible in many cases to get a material the width of which will equal the height of the wall space, and which may be run round the walls without many joints; where there are not many openings or recesses to be dealt with, they may be readily cut out of the material. This material may be used in narrower widths as a dado or frieze in combination with papered walls, or as a filling to panels.

Prepared canvas may be applied in a similar way to walls and ceilings, and afterwards decorated in either oil or water colour, and either of these materials not only forms a suitable decorative surface, but prevents the appearance of surface cracks, such as frequently arise with ordinary plastered ceilings.

Calculating Paper Required. The paperhanger is required to estimate the amount of paper required for any particular piece of work. The experienced man can tell pretty closely without measurement the number of pieces required for any particular room, but it is easy to ascertain the superficial area of the walls of any room, and, bearing in mind the amount of paper in a roll, already given, to see exactly how many pieces will cover it. But allowance must also be made for waste; this occurs not only in fitting paper round door and window openings, fireplaces, and recesses, which often accounts for a good deal, but there is also often considerable waste in cutting up paper so as to ensure that the pattern shall match exactly when two pieces are hung side by side. If the pattern is small, so that in height it exactly repeats every few inches, this loss will not be great, but if the pattern is large, and only repeats once or twice in the height of the wall, it may easily happen that a considerable amount may have to be wasted for every length cut from the roll. It is usual to allow one extra roll for each five to eight rolls required exactly to cover the wall, the specific allowance depending on the probable waste.

Trimming Paper. Wallpapers are delivered in rolls with a margin on each side, which must be trimmed off before the paper is hung. The machines used for trimming have been described, but the old-fashioned method of trimming, by means of a large pair of scissors or shears, still prevails. The roll of paper is laid on the trimming-board and unrolled, trimmed with the shears on one edge, and re-rolled during the operation, which is repeated for the other edge.

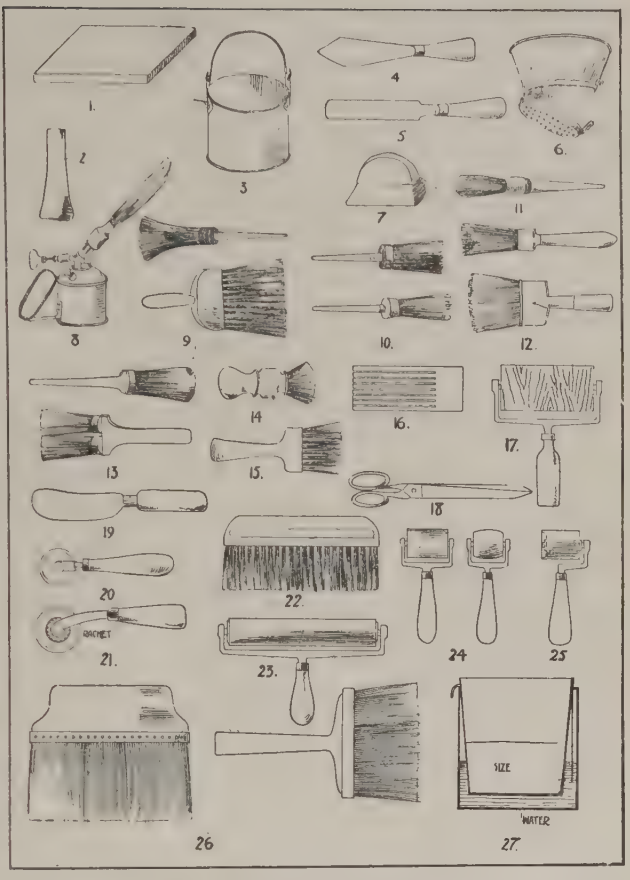
Preparing the Walls. In the case of new walls, the surface should be sized with glue size [see Painting, page 5497]. It is well to point out that in the case of most plastered surfaces the lime in the plaster is very liable to act on the colours used for printing designs on wallpapers, and also on ingrains, and destroys them. This action is worse if there is any damp, but may occur even with dry plaster, and may continue for several months at least after the wall is plastered. It is particularly likely to affect green and some other delicate tints, and it is desirable, as a rule, not to hang an expensive wallpaper on new walls within twelve months of the plastering, but to cover them temporarily with a tinted lining paper, or to distemper them.

In the case of old walls, it is important that the old paper should be stripped; if this is not done, the dirt, and possibly disease germs, in the old paper will only be covered over. Paper may be removed by washing it over with hot water, and then scraping it off, taking care not to damage the plaster. Paper that has been varnished after hanging is often very difficult to remove. A coat of hot paste applied to the surface will, as a rule, soften it, but a special varnish remover may be required, and in some cases where the paper was porous the varnish penetrates to the plaster, and it is almost impossible to remove it without destroying the plaster surface.

A varnished surface does not hold either dirt or germs to the extent that an unvarnished paper will, and the surface, if it is left, may be cleaned, and the joints rubbed smooth with pumice; the surface may be prepared by giving it a coat of brown sugar mixed with water in the proportion of 2 lb. of sugar to 1 pail of water.

Repairing Walls. In the case of old walls, all nails must be extracted and any defects in the plaster made good. This is properly the work of the plasterer, but the paperhanger may often have to execute small repairs. Such repairs are usually executed in plaster of Paris, or in plaster mixed with fine lime putty [see Plastering], and care must be taken to see that the surface of the repair is truly in the same plane as the general wall surface.

When plaster has been damaged by blows, which is liable to occur—as, for example, by the handle of a door opened back against it — ordinary repairing in plaster is useless. In such a case the plaster may be neatly cut out in the form of a square, and a piece of wood let in, screwed if possible to wood plugs let into a brick wall, or to the quarters of a partition, but in some cases merely to the laths. In this case, also, care must be taken to see that the surface is uniform with the wall, and if sunk a little below it, the extra thickness may be made up by pasting one or more neatly cut sheets of paper over it.



PAINTERS' AND PAPERHANGERS' TOOLS

1. Grinding stone 2. Muller 3. Paint-pot 4. Stopping knife 5. Palette knife 6. Strainer 7. Felt rubber 8. Painters' torch 9. Dusting brushes 10. Ground brushes 11. Sash tool 12. Varnish brushes 13. Distemper brushes 14. Stencil brush 15. Badger softener 16. Grainer's comb 17. Graining roller 18. Shears 19. Trimming knife 20. Cutting wheel 21. "Twentieth Century" cutter 22. Smoothing brush 23. Smoothing roller 24. Seam rollers 25. Side-arm roller 26. Paste brushes 27. Size kettle

Paperhangers' Paste. Pastes are employed by the paperhanger varying in strength with the class of material to be used. The following recipes are given in Rivington's work, and the best white wheat flour should be used as the basis of them all.

No. 1. Beat up 4 lb. of flour in cold water to a stiff batter, getting rid of all lumps; add enough water to bring it to the consistency of pudding batter. Pour boiling water over it, stirring rapidly; when the mixture swells and loses the white colour of flour it is ready for use.

No. 2 is made like No. 1, but, just before the boiling water is added, 2 oz. of alum are mixed with the batter; this hardens it and is a good preservative. This form of paste may be used for flock papers, but alum must not be used with gilt papers, as it turns the metal dark.

No. 3. Make a batter as in No. 1, but of less consistency, and to 2 qts. of batter add ½ oz. of powdered resin. Set the mixture over a moderate fire, stirring it till it boils and thickens; allow it to cool, and thin it with thin gum arabic water. This is used when strong adhesion is required, and is useful in papering over varnished or painted surfaces.

No. 4 is the same as No. 3, but without the gum arabic, and is used for securing the edges of flock papers.

Some special pastes for hanging heavy goods will be described later.

Hanging Wallpapers. Quite apart from the mere mechanical part of hanging there is need for a good deal of judgment in the setting out of the paper so that it will look well on the wall; it often happens that by shifting the paper up or down a few inches the effect may be considerably improved, or the reverse. It is very important also that any well-marked pattern should be properly centred in the most prominent feature in any room; this is very usually the chimney front. This careful

centring is, if possible, of even more importance in papering ceilings, for the whole expanse is seen at once, and if the pattern is not set out centrally in the room a very bad effect is produced.

Special care must be taken to see that the first strip hung on a wall has the edges truly vertical, and a line and plummet may be used to set out a vertical line, which may be marked on the wall surface with chalk.

Pasting the Paper. A length is cut off from the roll a little longer than the height between skirting and cornice, laid face downwards on the table, and the back pasted over uniformly and not too thickly, working from the centre outwards. After pasting, the ends are folded back towards the centre, the edges being kept even; if the strip is too long for the table, one end is first pasted and then folded over, then the paper is drawn along and the other end pasted and folded. The actual hanging requires skill and experience. The upper edge is usually cut exactly, and is fitted against the cornice mould or picture rail, and the upper half of the paper unfolded, placed in contact with the wall, and brushed down with a cloth, brush, or roller; care must be taken not to work the paste towards the outer edge or it may be forced out in lumps. When one piece is hung it serves as a guide to the others, which are added right and left. In hanging the last piece there may be some difficulty in matching exactly the patterns at the joint, especially if the design is large, and any such irregular join should be contrived where it will be as little obtrusive as possible. Where an angle occurs it is often found not to be quite straight, and it is best to cut the paper so that a join will come close to the angle and not to use a whole width. When each strip is hung the bottom edge usually overhangs the skirting slightly, and when it has been rolled or brushed down close to the bottom the lower end is lifted slightly, the point of the shears drawn along to mark the exact length, and it is then trimmed and afterwards pressed down. The narrow rollers are used for the joints. The joints are usually formed by butting one piece of paper close to the next piece, and where this is done both edges must be trimmed; in common work one selvedge is left on and the edge of the next piece pasted over it, but this causes a ridge at the joint. In arranging ceilings the paper should be set so that the joints run in the direction of the window, or if there are windows on adjoining walls then towards the strongest light. Where a good class of paper is hung on new walls they are often first hung with lining paper and then with the wall-paper itself.

Hanging Special Wall Coverings. Where heavy, embossed papers are employed it is usual to prepare the wall by hanging strong brown paper as a lining. In the case of most kinds of special hangings full instructions are issued by the makers and these should always be observed.

Lincrusta Walton, if the weather is cold, should be placed in a warm room before it is unrolled. The edges must be trimmed very carefully, using a metal-edged straightedge and a sharp leather-cutter's knife, which is stiffer than a paperhanger's. The paste is used hot and the lengths, after pasting, are applied to the wall, and well rubbed with a stiff, short hairbrush, or a soft, spherical rubber roller. If blisters appear they must be pricked and then rubbed down. The paste may be ordinary paste mixed with half the amount of glue, but the following composition is recommended by the makers: French plaster of Paris, 4 lb.; raw linseed oil, 1 pint; these are rubbed together through a sieve; 1 lb. of white glue is well boiled in 1½ gallons of water and poured in hot, and the whole left to get cool, being stirred to thoroughly mix it.

Anaglypta is trimmed with a metal straightedge and pasted with ordinary paste; after about fifteen minutes it is again pasted with stiff paste containing from ⅛ to ¼ glue, hung at once, and pushed home with a cloth.

In hanging *Lignomur* no glue must be used, but the paste should be as stiff as it can be made. Tynecastle canvas is treated in the same way as Lignomur, but it is not necessary to mix glue with the second coat of paste.

Japanese leather papers are hung with ordinary paste, applied to the paper as a first coat, and after two or three minutes a second coat is applied, mixed with a proportion of glue.

PAINTERS' WORK

The work of the painter consists in covering perishable or common materials with a thin material that will protect them from decay, enable them better to resist ordinary wear and tear, or give to them an improved appearance.

Painters' Tools. The painter's tools are comparatively few in number. A *grinding stone* [1] is required for grinding colours; this is usually a slab of marble about 2 ft. square; the *muller* [2] is about 7 in. long and 4 in. in diameter, and is of granite or other very hard material. Where paint is required in large quantities it is, however, ground in a mill. There are also *pots* of earthenware or tin for holding colours of various sizes, a *pallet* to hold small quantities of colour for use in letter writing and small decorative work, and a *mahlstick*, used as a rest for the hand in letter writing and small decorative work.

The *stopping knife* [4] is one with a stiff blade set in a wooden handle. From the handle the blade broadens outwards, the back is straight till the broadest point is reached, and the end is rather sharply pointed; the lower edge is without a sharp angle, but is slightly rounded so as to form the point. This tool is used for *stopping* surfaces that are to be painted—that is, filling in any small holes with putty or other special stopping.

The *palette knife* [5] is one with a long, broad, flexible blade, parallel sided, and with a rounded end fixed in a wood handle. It is made in several sizes and is used for mixing paints.

The *painter's can* [3] is a circular metal case with a flat bottom and a movable handle of iron, by which it is carried; it is used for mixing paints and for containing them during use.

A *strainer* is used for straining paint after it has been mixed, and, before use, to rid it of all irregularities and lumps. Strainers are of various forms: the simplest resembles an ordinary colander but with a flat bottom, which is perforated with very fine holes, through which the paint is passed, a stick or brush being employed to work it about and assist it through. Another form [6] has a hinged bottom perforated with large holes, and over these a piece of muslin or cheesecloth is strained, and this material, if it becomes clogged with particles of paint, can be renewed at any time.

The *felt rubber* [7] is a flat tool formed at the back into a handle and covered with felt, and is specially used for rubbing down varnished work.

The *painter's torch* [8] is a small lamp, producing a strong flame with a forced draught, which is used for burning off paint, and can be held in the hand and moved over the surface of the paint to be

removed; where gas is available a burner on the principle of a Bunsen burner, producing a flat flame, may be used for the purpose.

Brushes are the most important tools the painter uses, and with these the material is actually applied to the surface to be covered; they are made in various sizes and forms, depending on the nature of the material to be employed and the method of using it. Good brushes, if properly cared for, will last a long while, and it is desirable they should be of good quality and made by a firm of standing.

Dusting brushes [9], both round and flat, are required to prepare work for painting; like other brushes these are provided with wooden handles, are of different sizes, and are kept dry for dusting only.

Brushes for applying paint differ much in size and form, each class of brush being made in a series of sizes, which are regularly numbered.

Ground brushes [10] are fairly large brushes employed for large, plain surfaces and are made round or oval in form; they are formed of hogs' bristles and are well bound round at the base with twine to keep the bristles compact, or have patent metal ferrules.

The *sash tool* [11] is a smaller class of brush, used for painting mouldings, sash bars, and similar work. These are also made in different forms, but an oval-shaped brush is very generally used.

Varnish brushes [12] are either round brushes brought to a broad thin edge or are broad brushes mounted in a metal frame.

Distemper brushes [13] are large brushes used for whitewashing and distempering; they are termed *one-knot* or *two-knot*, according to the manner in which they are made up; and flat brassbound brushes are also employed for this work.

Stencil brushes [14] are used for stencilling designs in distemper, and are short metal-bound brushes.

A *badger softener* [15] is a brush used in graining work to give a woody appearance to the work.

Care of Brushes. It is important that brushes, if they are to be kept in good working order, should not become caked with paint. It is not necessary to clean brushes after a day's use if they are to be used again within a day or two, but they should be suspended in raw linseed oil or in water to keep them moist, and so that the points do not touch the bottom of the vessel; for if the bristles rest on the bottom they are apt to be bent.

The oil or water can readily be squeezed out of the brush by drawing it firmly across the edge of a piece of board when the brush is required for use. If brushes are to be out of use for some time, they must be thoroughly cleaned in turpentine or with soap and hot water, dried, and afterwards wrapped in clean paper and put away in a dry, cool cupboard.

Grainers' combs [16] are required for work to be grained, and these are made in various degrees of fineness.

Graining rollers [17] are employed for some kinds of graining. The colour is supplied by a brush to a series of discs on the roller, which are notched at intervals, and produce dark broken lines in the work, or the roller may have the pattern of the grain incised on its surface.

Pumice-stone is used for rubbing down work before applying fresh coats of paint, and fine glasspaper is used in a similar manner.

Paint-spraying machines consist of a pumping apparatus attached to a hose fitted with a perforated nozzle; they are chiefly used for distemper, lime white, etc., and the material is sprayed on to the surface very rapidly and evenly, and reaches all crevices or irregularities.

Painters' Materials. The materials used by the painter are either opaque, so that they entirely cover and conceal the real surface of the material, or they are transparent or semi-transparent, allowing the natural surface to be visible.

Of opaque materials, those in most general use are termed *paints*, and when mixed ready for use are usually made up of *vehicles* (which are liquid substances holding other matters in suspension, and permitting of their even distribution over the surface), *driers*, which are oxidising substances enabling the vehicles to dry rapidly, and *pigments*, or colouring materials. Pigments are finely powdered, and held in suspension by the vehicles.

Vehicles are of different kinds. For water-paints, ordinary water is used, and this class of vehicle is employed not only for water-colour drawings, but for whitewash and distemper. For most painted work, however, the vehicle is either a fatty or fixed oil—that is, one that cannot be distilled, or a volatile oil that may be distilled; and not uncommonly both these classes of oil are employed in mixing paint for use.

Oils. *Linseed oil* is the most usual of the fixed oils, and is obtained by crushing the seeds of the flax plant. In common with other fixed oils, it does not dry by evaporation but by the absorption of oxygen, and during the process attains great toughness and flexibility. When applied to wood surfaces, it sinks into the pores of the wood, and hardens, forming a protection from the weather.

Raw linseed oil is the oil in its natural state. In this condition it is of a bright amber colour, and dries somewhat slowly. If spread in a film on a non-absorbent material it takes from two to three days to dry; the bright colour makes it unsuitable for mixing with delicate shades, and if it is to be used for such work it may be clarified with oil of vitriol, which must, however, be afterwards washed out. The material improves in quality and colour by keeping for some years, and should not be used until it has been kept for six months at least; it is generally employed for most internal work in which linseed oil is the vehicle and for grinding up colours.

Boiled linseed oil absorbs oxygen more rapidly than the raw oil. The process of boiling consists in heating the oil (which does not actually boil) to about 200° F., and then adding to each gallon of oil about 1 lb. of red lead and 1 lb. of litharge, and raising it to a temperature of 400° F., which is maintained for two or three hours. If a dark-coloured oil is required, umber may be added also during the boiling process. The oil, after boiling, is drawn off and allowed to settle, and is then bright and clear, but darker than the raw oil.

If the oil is to be mixed with zinc-white as a pigment and not white lead, the oxides of lead should not be used in the boiling process, but about 5 per cent. by weight of powdered peroxide of manganese is substituted, and the oil is afterwards filtered. The drying and the colour of raw oil may be improved "by adding about 1 lb. of white lead to every gallon of oil, and allowing it to settle for at least a week" ("Builders' Work"—Seddon).

The boiled oil dries more quickly than the raw oil; if spread on a non-absorbent material it should be quite dry in from twelve to twenty-four hours. It is particularly well suited to external work, when rapid drying is of great importance, and in which tints of a delicate nature are rarely called for.

Poppy oil is extracted from the seeds of the common poppy; it is inferior to linseed oil in both tenacity and in its drying qualities, but is very

nearly colourless, and is therefore sometimes employed for mixing with delicate tints in internal work.

Nut oils are usually extracted from walnuts, and are cheap, but not durable, and are suited only for internal work of a temporary character.

Turpentine. *Oil of turpentine*, also known as *spirits of turpentine*, abbreviated commonly into *turps*, is a volatile oil obtained by distilling turpentine—a resinous exudation from certain trees which contain resin and oil of turpentine. This oil has a strong odour, and when exposed to the air absorbs oxygen, and is converted into a substance resembling resin. It is used as a solvent for gum resins, and also for mixing paints in combination with linseed oil, or by itself when a flatting coat is required—that is, one without a glossy surface. When spread on a non-porous surface it should dry in twenty-four hours, leaving a hard varnish on the surface.

Strasbourg turpentine is produced from the silver fir, *Venice turpentine* from the larch, and *common turpentine* from the Carolina pine.

Driers. *Driers* are mixed with paints to assist the drying of the vehicles when this is necessary. The drying of linseed oil is produced by the absorption of oxygen as already mentioned, and the driers which are usually employed are materials rich in oxygen, and readily yielding up the oxygen to the oil, thus hastening the process. The action of some of the pigments to be hereafter described is to retard the drying process, and driers are specially valuable when such pigments must be used in mixing paints, otherwise the paint would continue for a long time in a semi-dry condition, known as *tacky*. During this time it is slightly sticky, or adhesive, if touched.

The most usual driers for use with light tints are *acetate* or *sugar of lead* and *sulphate of zinc; litharge*, or oxide of lead, which is produced during the extraction of lead from its ores, is very commonly used for all darker tints. For use with lakes, *japanners' gold size* is used, which consists of oil boiled in litharge. For use with zinc-white, *sulphate of manganese* is an efficient drier, a very small quantity sufficing; but care must be taken in mixing it or the paint may be spotted. Another drier used with zinc-white is that made by adding about 10 per cent. by weight of a mixture formed of boiled linseed oil (20 parts) and peroxide of manganese (1 part). It is important to select a drier suited to the pigment to be used, and to observe the following points, which are taken from Seddon's "Builders' Work."

1. Do not use them with pigments that dry well in oil colour.
2. Do not employ them to excess, which would retard the drying.
3. Do not add them to the colour till just before it is used.
4. Do not use more than one drier with the same colour.
5. Avoid the use of patent driers.

The result of using driers in excess may be the drying of the surface with abnormal rapidity, so that a thin skin is formed which, at a later time, may become softened by the action of the undried paint behind it, and remain tacky for a long time. Patent driers are in the form of paste, and are slightly more economical than the ordinary liquid driers, but vary much in quality and in their effect on the paint.

Pigments. *Pigments* are the solid matters introduced into paints to give *body*—that is, solidity—substance, and opacity to the paint, and also to give to it any desired tint or colour. They are in most cases earthy or metallic carbonates and oxides, and are very finely ground; they are sold in a dry form as powder, and also ground up in oil. They may be divided into two main classes—namely, *bases*, which are used to produce body and opacity, and *colouring pigments*, which are used to produce various tints and colours, especially in the finishing coats.

Bases. *White lead* is prepared by various processes. The Dutch process produces the best, and consists in placing gratings of pure lead in tan. The fumes of acetic acid are allowed to act on these, which become corroded and covered with a crust of *carbonate of lead*, which is commonly known as *white lead;* this is removed and ground and forms a heavy powder, which becomes grey if exposed to the air. The substance may also be prepared by passing carbonic acid through solutions of various salts of lead, but the material thus precipitated has no density, and absorbs more oil than that produced by the other process.

White lead is the most usual base for oil paint and has a very high covering capacity. It is, however, injurious to those who use it, and is very liable to be discoloured by many chemical gases, such as sulphuretted hydrogen. It should be old and not freshly made, or the paint soon loses its whiteness, but it must be protected from the air till use. It is extremely liable to adulteration, and can be relied on as pure only if obtained from the manufacturer as *genuine dry white lead*, either in lump or in powder. The materials used for adulteration are sulphate of baryta (which is similar in appearance but heavier than white lead) and whiting, which is lighter. White lead, if pure, should weigh about 400 lb. per cubic foot, and if either adulterant is used singly adulteration is detected by the variation in weight, but if the two are combined the weight may be accurately adjusted, and only a chemical test will reveal the adulteration.

White lead is often sold mixed with sulphate of baryta, which does not cover so well when mixed with oil, and when the two are mixed in equal proportions the material is termed *Venice white*, while *Hamburg white* has 1 part of lead to 2 of baryta, and *Dutch white* has 1 part of lead to 3 of baryta.

Red lead is produced by raising *massicot*, or oxide of lead, to a high temperature, during which process it absorbs oxygen and becomes converted into red lead, also known as *minium*. This material is durable if used pure and alone and not exposed to the action of acids or impure air. It is obtainable in the form of a powder and is sometimes adulterated with brickdust. Red lead is sometimes used as a drier, and it is used mixed with white lead and oil for the first coat of paint, termed *priming*, in joinery, and for the first two coats on ironwork.

Antimony vermilion, a sulphide of antimony, is sometimes used in place of red lead; it is obtained in a fine powder and is of a brilliant colour when ground in oil, and is not affected like red lead by impure air or acids.

Zinc oxide is frequently used as a base for paints; it is not poisonous like white lead, and is not liable to be discoloured by chemical fumes. When ground in oil it requires much more oil than white lead, and will require less to thin it. If it is used to give a white finish it should be mixed with refined linseed oil to secure a perfectly white surface, but this is not necessary with darker tints.

Colouring Pigments. The *colouring pigments* are much more numerous than the bases;

lists of the most usual pigments may be consulted in Seddon's "Builders' Work," under Painter, or in Rivington's "Notes," Vol. III.—Materials. These lists supply information not only as to the colour of the various pigments, but as to their nature and properties, and form a good guide as to those which may safely be used under varying conditions, and as to others which cannot be relied upon as permanent, especially if subjected to certain influences.

Mixing Paints. The proportions of the different ingredients required in mixing up paints for use necessarily vary under changing circumstances, and in particular with the nature of the material to which they are to be applied. Iron, wood, and plaster, for example, will require the paint that is to be applied to them, and in particular the first two coats, to be differently prepared, the more absorbent material requiring the use of a higher proportion of oil. The colour effect required to be produced necessarily affects the selection and the amount of colouring pigment to be added; where very delicate light tints are to be used this may affect the selection of the class of oil to be employed. The question of whether the paint is to be used for internal or external work has an important bearing on the question; in the latter case boiled oil is generally selected, on account of its superior weathering qualities. Turps is included in most paints as a thinner, its object being to reduce the consistency of the paint at the time it is applied, but it eventually evaporates and does not form a permanent ingredient.

Variation in Successive Coats. In painting any piece of work the ingredients will vary in successive coats. On any porous substance the first coat in particular must have a liberal supply of oil, which tends to sink into the pores of the material and dry there. Subsequent coats will require a certain amount of turps to make them work freely, and in painting on old work the first new coat is always mixed with a liberal amount of turps, which makes it adhere to the older work. The colouring pigments are usually mixed in with the two final coats, the last one of all being relied upon to produce the exact tint required, though the one immediately before has an important influence often on the final appearance.

Apart from any other consideration, the knowledge and skill of the individual painter always is an element in the mixing of paints; these have to be acquired by experiment and practice, which, when attained, are better than any hard and fast rules as to the proportions of ingredients.

Method of Mixing Lead Paints. If the pigment is in the form of powder it is ground up with raw linseed oil with the muller on the grindstone, and is reduced to the consistency of a thick paste, but in many cases it is purchased in this condition; if only a small quantity is required, as in the case of a colouring pigment, the paste is worked up by means of a palette knife on a slab, with the addition of a little oil and turps; but when a considerable amount is to be mixed, a painter's pot is used. The pot is first rinsed round with a little oil to prevent the white lead adhering, and then the latter is placed in it, and oil and turps added by degrees, and the lead well worked round with a stick, which may be shaped something like an oar, till the lumps are all reduced and the consistency of the whole is smooth and uniform, the palette knife being used in this operation.

If the paint is to be coloured, the colouring pigment, also ground in oil, may be added to the white lead and worked up with it if the exact proportion required is known; but it is usually better to thin it, and work it up separately, and add it to the white paint in the pot a little at a time till the exact tint or tone required is arrived at.

Adding Driers and Straining. The driers are added to the paint at this stage, and here again exact proportions cannot be given, as these vary with the nature of the drier and other circumstances; but the proportion is always small, and if a good drier is used, about 2 per cent. by weight should suffice. The rules as to the use of driers already given must be borne in mind, and in the case of a priming coat to which red lead is added, any other drier may often be omitted.

Straining the Paint. The last process in the way of preparation consists in carefully straining the paint. If this is not done, small specks and impurities are likely to be left in it, and good work will be impossible. In some cases it is useful to strain the paint two or three times. The strainer already described is made use of, the paint is poured into it, and allowed to drain out into a clean paint-pot, and it may be stirred with a stick or brush or palette knife to help its passage through the sieve, which must be carefully cleaned after the operation so as to be ready for future use.

Seddon's "Builders' Work" gives the following table of the approximate quantities of materials required for painting four-coat work to finish white and the superficial area covered by each.

Priming Coat. 10 lb. genuine white lead, 1 oz. red lead, 2 oz. litharge; or 1½ oz. litharge, ½ oz. burnt white vitriol, and 4 pints raw linseed oil. Will cover about 63 yd., varying with the absorbent properties of the surface.

Second Coat. 10 lb. genuine white lead, 2 oz. litharge, 2½ pints raw linseed oil, and 1½ pints turps. Will cover 100 super. yards.

Third and Fourth Coats. 10 lb. genuine white lead, 2 oz. litharge; or 1½ oz. litharge, ½ oz. burnt white vitriol, 2 pints raw linseed oil, and 2 pints turps. Will cover 113 super. yards.

Flatting Coat. 10 lb. genuine white lead and 4 pints turps. Will cover 150 superficial yards. To give a very pure white, ½ oz. ultramarine may be mixed with the last coat, and for coloured paint 1 to 2 oz. of colouring pigment with each of the last two coats.

Special Forms of Paint. A large number of specially-prepared paints are now manufactured by different firms, and supplied ready for use, or requiring merely the addition of some thinning material in accordance with instructions issued by the manufacturers. It is impossible to describe or even give a full list of such paints, but many of them are designed for work in special situations, and they include various forms of enamel paints. In all cases it is necessary carefully to follow the instructions issued by the makers, and in most cases several colours can be obtained in most of the different brands.

Applying Paint. The paint is transferred from the pot and applied to the surface by means of paint-brushes. For plain surfaces a *ground brush* of suitable size is dipped into the paint, taking up a moderate amount, and any superfluous paint is wiped off against the sides of the pot. The brush is held at right angles to the face of the work, so that the ends of the hairs force the paint well into the pores, and the brush must be applied vigorously. Work is usually begun at the top, and brought down, and in painting panelled

work, such as doors, the frames are usually first dealt with, then the panels. When paint is applied to the edges of any object, such as a door, in order to avoid an excess of paint at such points the brush is drawn a little away from the edges in working. Mouldings are particularly liable to collect excess of paint, and for such work it is used somewhat sparingly. When two or more colours have to be used it is necessary to take care that the edges of the colour last applied are very carefully cut in a true straight line to avoid irregularities; so also where painted work has to be finished against some other substance, as, for example, when sash-bars in a window are painted it is a sign of poor workmanship if the glass itself is smeared with paint where it adjoins the bars.

Preparing Surfaces. Before applying paint to any surface it is necessary to see that it is perfectly clean and free from grease, otherwise the paint will not adhere. It is desirable in the case of woodwork that the wood should be dry, for any moisture will be imprisoned by the coat of paint, and will not be able to dry out later. In the case of resinous woods any knots showing on a surface to be painted must be dealt with, or they will be liable to exude turpentine, and damage the work, and this process is described as *knotting*. Knots may be killed by painting with hot lime, and, when this is dry, ironing them with a hot iron and finally rubbing them smooth with pumice-stone; or the lime may be scraped off after twenty-four hours, and the knots painted with a mixture of red and white lead and linseed oil; and when this is dry the pumice-stone must be applied. It is a quicker and more usual process to cover the knots with a material termed *knotting*. This is usually *patent knotting*, a mixture of shellac and naphtha, which dries in a few minutes, leaving a protecting skin. *Red lead knotting* is also used, and is made by grinding red lead in water and mixing it with strong glue. This is applied hot, and dries in a few minutes. If, in spite of such treatment, knots still show through after the third coat is applied, they may be covered with gold or silver leaf, fixed on with size.

Priming. *Priming* is the first coat of paint applied. For woodwork it is usually formed of white and red lead mixed with raw linseed oil. A little litharge ground in turps may be added as a drier. This coat is intended to sink well into the pores of the wood and to fill them up, while at the same time the red lead hardens and forms a surface for the succeeding coat.

Clearcolle is sometimes used, but does not enter the pores, and may peel off; it should only be used for internal work, and then only if the surface has become greasy or dirty, and will not take the ordinary priming.

Stopping. *Stopping* is done with *putty*, which should be made from dry whiting kneaded up with raw linseed oil, and with the addition of a little white lead. It is applied with the stopping-knife to fill any holes in the wood. The stopping hardens in the holes, and forms an even surface for painting. In the case of coloured woods to be varnished or polished the stopping may be tinted to match the wood. Stopping should be done after priming, or the oil in the stopping will be sucked out of it by the wood.

Subsequent Coats. If the work is to be finished white or a light tint, all subsequent coats must be kept light, or they will not be fully covered by the final coat; but if the finish is to be dark the earlier coats may also be dark, and are usually of a different tint to the final coats. The reason for this is that if all the coats were of the same colour parts of the work might be easily overlooked in applying one of the coats.

The priming coat is well rubbed down with sandpaper, glasspaper, or pumice-stone before the next coat is applied, and each subsequent coat, when it is dry, is examined, and any irregularities rubbed down.

Flatting. When it is desired entirely to avoid a glossy surface in the finishing coat—and this is often a desideratum—the previous coat is mixed with a larger proportion of oil than it would ordinarily have, and the final coat is mixed with turps only. It should be applied before the previous coat is quite hard, and dries without any gloss. Such a coat will not stand washing like a coat mixed with oil, and to overcome this a little size or raw oil that has been bleached is added, and this is termed *bastard flatting*.

Graining and Varnishing. This method of finishing paint is much less used than formerly. It is more expensive to execute, but, if well done, it will wear for many years if carefully treated and given a coat of varnish from time to time. The reason for its disuse is mainly an æsthetic one—namely, that it is confessedly a sham, and that it is more artistic to treat work that is covered with paint frankly as a painted surface, and not to attempt to make it resemble a costly wood. This method, however, for office work and for the offices of good houses, is so durable and useful that it is never likely to be abandoned entirely. For work that is to be grained the priming and two or three colouring coats are laid on as usual, and the ground is then prepared of the general colour of the wood to be imitated, and this is allowed to dry. The painter then mixes in a palette colours similar to the darker grains of the wood, and these are laid over the ground, and, while still wet, painters' combs [16] are drawn over it to give the effect of graining. For fine work camel-hair pencils may be used, and the effect of knots is produced by using sponges or pieces of cloth. This work requires considerable skill and practice if the graining of highly ornamental woods, such as maple and walnut, is to be faithfully represented, but a common class of graining can be executed without much difficulty.

Overgraining consists of applying a thin extra coat of raw umber or vandyke brown, mixed with small beer, over the ordinary graining. This is applied with a large flat brush with a wavy motion, and is intended to represent the effect of silver grain.

The varnish is applied after the graining is dry, and should consist of two coats of copal varnish.

Painting Iron. The surface of the iron must be clean and free from rust, and it is often usual to paint iron with one coat directly it leaves the forge or cast. It is customary to employ red lead or an oxide of iron paint. Ironwork should have another coat of paint before fixing, and, where exposed, a total of four coats. In painting rain-water gutters and heads, both the inside and the outside must be painted. In the case of ironwork that has been dipped in Dr. Angus Smith's solution, a coat of knotting is required before painting.

Repainting Old Work. Old work requires to be thoroughly cleaned before repainting; it must be well washed with soap and water, and afterwards rinsed with clean water, and rubbed down with pumice. The first coat of new paint should be mixed with a liberal supply of turps. If the old paint is worn in places so as to expose the joinery, it must have additional coats of paint over such parts; these are first executed and

allowed to dry, and the final coats carried over the whole uniformly. Where joinery has been repaired with new woodwork, this must be treated as new joinery—primed, stopped, and two coats of paint applied. This is described as *bringing forward*, and the final coats are taken over old and new work alike. If old paint has perished or become blistered so that it is impossible to make a good job by painting over it, it must be removed ; on iron this is done by scraping, and on woodwork by burning off, a jet of gas or the painter's torch being used against the paint, which is thus softened and easily scraped off. A solution of equal parts of soda and quicklime may also be used ; the soda is dissolved in water, the lime added, and used hot with a brush, after which the paint can be washed off with hot water. If this is used the wood should be washed over with vinegar before repainting to kill the lime.

Varnish. *Varnish* is a transparent material which may be applied to natural surfaces or to surfaces already painted. Varnishes are solutions of resins or gums dissolved in spirits or in oil. Resin is the residue obtained by distilling turpentine. There are several varieties of resins, and some of them are termed *gums*. These are exudations from trees, and are, when first produced, mixed with some essential oil, which, evaporating, leaves a hard substance.

The principal resins in use for varnishes are as follow. *Amber*, obtained from Prussia, very hard and durable, but difficult to dissolve, expensive, and a slow drier. *Copal*, obtained from the East and West Indies and America, may be obtained in three different qualities, depending on the colour, the lightest being very pale, and used for high-class work. *Mastic* is a resinous gum obtained from the countries bordering on the Mediterranean. *Gum Dammar* is obtained from the kauri pine, is rather soft, and almost colourless. *Lac* is a resinous substance obtained from the East Indies ; from the natural substance *shellac* is manufactured, which is very pure, and is used in making lacquers. *Sandarach* is a somewhat similar substance, obtained from the juniper. *Common resin* is either brown, which is formed by distilling the turpentine of spruce fir in water, or white, which is distilled from Bordeaux turpentine.

The *solvents* (which correspond to the vehicles in paint) are *boiling linseed oil* used with the hardest resins and gums. Varnishes made with oil are the hardest and most durable, but take longer to dry ; they are used for superior work, and should be employed for external work. *Turpentine* is used with softer gum such as mastic, dammar, and common resin. These varnishes are less costly, and dry quickly, but are not so durable as oil varnishes.

Methylated spirit is used with lac and sandarach. These spirit varnishes are known as *lacquers*, dry quickly, and become hard and brilliant, but are apt to crack and peel, and are used mostly for cabinet work not exposed to weather.

Water is used hot with lac and with as much ammonia, borax, potash or soda as will dissolve the lac. This is inferior to the other varnishes. *Driers* are used with varnishes, and accelerate the drying, but if used in large proportions injure the durability. The usual driers are *litharge*, *sugar of lead*, or *white copperas*.

Work of a porous nature such as wallpaper or wood must be sized before varnishing, and no second coat of varnish should be applied till the coat below is thoroughly hard, or the drying of the lower coat will be stopped.

Staining. Stains are applied to light-coloured woods that are to be varnished. In some cases the colouring matter is mixed with the varnish, but it is usual to stain the wood with a liquid water-stain, then to size twice, and in good work to varnish the surface twice. In the case of floors, the margins of which are often so treated, the varnish is very apt to wear, and instead of varnishing, the work may be wax polished. The polishing is done with beeswax shredded, mixed with turpentine, and gently heated ; the wax is applied with a rag and then vigorously rubbed with a cloth or, if a large area is dealt with, by a floor polisher. This work must be kept in good order by rubbing over about once a week, and maintains a better surface than varnished work, but demands more attention. The stains are supplied in various colours, to imitate different classes of wood, such as rosewood, walnut, oak, mahogany, etc., and also in other colours, such as green ; they may be obtained in a liquid state ready for use, or in powder, which is dissolved in hot water for use ; it is laid on with a brush or sponge in one or two coats, according to the colour required, and allowed to dry before sizing.

Applying Varnish. Care and judgment are required in varnishing ; the material is sensitive to atmospheric effects and should not be applied when there is much humidity in the atmosphere ; newly varnished work must be protected from cold draughts. The varnish, until used, must be stored in a warm place and not become chilled ; varnish should not be mixed with any other kind of varnish nor thinned with oil. The varnish is applied with a varnish brush, and is usually applied across the work and finished by stroking the work down with the brush in a vertical direction to make it flow and obliterate brush marks. Care must be taken not to apply too much varnish, especially at the angles, or it will run and form tears.

Whitewashing. This term is properly applied to the whitening of internal walls and ceilings with a mixture of whiting and water mixed with size, but is also sometimes used for the covering of walls with a mixture of lime and water, which is more properly described as *lime-washing*. Lime-white and common distemper are often applied by the plasterer, but will be described here. *Lime-white* is made from pure chalk lime mixed with water. Factories and other buildings are required to be lime-whitened at regular intervals, and the material for this purpose should be applied hot. The lime is first slaked, and, when slaking is complete enough, hot water is added to dissolve the lime ; 1 lb. of pure tallow may be added to each bushel of lime or 4 lb. of sulphate of zinc and 2 lb. of common salt. Lime-whiting is also applied to the walls of cellars and similar offices. It is cheap, but will not withstand wet, and is liable to rub off, but is serviceable when it is desirable to renew a coat at short intervals of time.

Whitewash is made with *whiting*, which is white chalk finely powdered, and is sold in the form of balls. The balls are roughly broken, soaked in water, and stirred and broken up with a stick, or by hand, and left just covered with water for about six hours ; afterwards double size in the proportion of 1 quart of double size to 6 lb. of whiting is added and the mixture left to stand in a cool place till it becomes a jelly ; then it is diluted and used. One pound of jelly will cover about six superficial yards.

Size. *Size* is liquid glue prepared by boiling down the horns and sinews of animals ; *double size* is the same material, but boiled down to about half the bulk, and is therefore stronger ; both these forms require soaking before use. *Patent size* is a

preparation of gelatine, and can be used without soaking.

Clearcolle is a coat of size mixed with water, which is laid over plaster walls and ceilings before whiting or distemper.

In mixing whiting for ceiling work some colour is mixed with it to counteract the yellow effect of pure whiting. This is termed *breaking down*—a little ultramarine or indigo, or sometimes black, if a dead white is required, but with tinted walls a warmer tone may be preferred for the ceiling, and a cream colour may be formed by adding ochre.

Distemper is formed of whiting and size with the addition of colouring material to produce any desired tint; the pigments are the same as used for oil paints, and are mixed with the whiting before the size is added. All distempers appear much darker when wet than dry. The real tint of any colour as mixed should be judged by applying some of it to a piece of white paper, and drying it artificially.

Washable distempers are specially prepared and sold in the form of paste; they require diluting with water before use, and must be mixed in accordance with the instructions given by the manufacturers. They may be obtained in a great variety of tints and colours, and form a good solid surface, which will stand washing.

Applying Whitewash or Distemper. This is done with a large brush [13] with a long wooden handle. The brush is dipped well into the pail of whitewash, and any superfluous material squeezed off against the edge; the brush is then applied smoothly and evenly to the work. The distemper should be stirred from time to time with a stick, and work should not be gone over twice.

Stencilling. Very good effects may be produced by stencilling a design on a plain coloured surface to form a border or line or to cover the surface generally. The pattern is cut out of a thin plate which is also provided with guides to indicate exactly the position it must occupy when shifted. Stencils may be comparatively simple or elaborate. Sufficient substance must be left in cutting the stencil to keep all parts of it connected together, and these ties should form an element in a good design. The stencil is placed against the finished surface of the wall, and a stencil brush [14] is dipped into the colour, which is darker than the ground, and is dabbed gently and evenly over the whole stencil. It must be held at right angles to the surface or the colour may run under the stencil plate and spoil the design. A design thus produced forms an excellent frieze to a plain distempered wall.

Tar and Pitch. Tar is obtained by the slow combustion of resinous woods, and such tar is known as *Stockholm tar*, as it was formerly almost exclusively imported from Sweden; it is thinner than coal-tar and of a rich brown colour, and penetrates well into the pores of the wood.

Coal-tar is a by-product of gas-making, and is formed by the distillation of coal; it is quite black in appearance and thick.

Pitch is the solid residue obtained by distilling tar; the process varies somewhat according to the nature of the wood from which it is obtained. Pitch may be added to coal-tar in the proportion of from 1 to 2 lb. to each gallon of tar. The object is to prevent the tar from running under hot sunshine, and, if used pure, it is apt to do so; a little lime is sometimes added with the same object. Pitch may also be added to Stockholm tar, but will destroy the bright, clear colour and make it nearly black, which is a serious objection if used for ornamental timbering in half-timbered gables and similar situations. Tar is applied hot, with a long-handled brush, and is principally used for timber work, especially fences and out-buildings much exposed to the weather, but is sometimes applied to exposed walls to render them waterproof.

Tar is also applied sometimes to rough ironwork, and forms a durable covering. Two coats should be used, and a little lime or sand may be mixed with it, and worked on with a hard brush.

Tar paint is used for some iron structures, such as bridges; the best mixture is said to be ½ lb. sulphate of lime, 1 gallon coal-tar, and sufficient naphtha to make it work freely.

GLAZING

The work of the glazier consists in cutting glass to fit openings of various sizes and shapes and in fixing it into frames of wood or iron, and sometimes into openings of brick, stone, or terra-cotta, and the making up of designs in small pieces of shaped glass termed *lead lights* and fixing them, and of similar work.

The glazier's tools consist of a *diamond* [28], which is used for cutting glass. This is a small uncut diamond set in lead and mounted in a brass ferrule with a hardwood handle. *Compasses* provided with a socket on one leg into which the handle of the diamond can be fitted for cutting circular work. *Hacking-out knife* [29], often a broken table knife, sharpened on the edge, and used for cutting out old putty in reglazing.

These are the principal special tools: but several others are used, already described in other trades —*square, straightedge, rule, claw hammer* (for sprigging), *stopping knife* (for stopping-in and smoothing off putty), *dusting brush, sash tool* (for priming sashes, painting putties, etc.), and, in lead glazing, *copper bits* or *soldering irons*.

Composition and Forms of Glass. The ordinary glass used by the glazier is composed of a mixture of pure sand, soda and chalk, and broken glass; these materials are melted at a high temperature and by various processes, and are then formed into sheets of convenient size and thickness for glazing purposes.

In all forms of glass large sheets are charged at a higher price per superficial foot than small ones, as the latter can often be cut from waste or breakages. Any glass that is required to be bent is charged at a special rate if bent in one direction, and a further charge is made if bending in two directions is required.

The principal qualities of glass in ordinary use are *crown, sheet glass*, and *plate glass*, which differ from each other to some extent in composition, but mainly in the method of their manufacture.

The maximum size of a sheet of *crown glass* does not exceed five superficial feet, and the thickness varies somewhat. The weight is about 13 oz. to 1-16 in. of thickness, and, for window glazing, should be about 16 oz. per foot. The glass is sold either in crates of tables containing half table, semicircular in form, or in crates of slabs cut to sizes. This glass is very clear and white, but the surface is considerably curved unless specially flattened, which makes glazing difficult, and it can be used only for frames of a small size. There are several qualities—*selected qualities*, for glazing pictures, of which A is the best and B the second; ordinary glazing qualities, divided into *bests, seconds, thirds*, and *coarse*.

Sheet glass has to a great extent superseded crown glass for most purposes. The surface may be polished or ground, and the glass bent to curves

if required. This glass is made quite clear, known as *crystal* or slightly tinted; it is to be had in the same qualities both for pictures and glazing as crown glass; it is usually described by its weight per superficial foot; the usual weights and thicknesses are as follow: 15 oz. = 1-15 in.; 21 oz. = 1-10 in.; 26 oz. = 1-9 in.; 32 oz. = 1-7 in.; 36 oz. = $\frac{1}{6}$ in.; 42 oz. = $\frac{1}{5}$ in.

This glass is not quite so clear or white as crown glass, but it can be obtained in much larger panes, because the sheets, being rectangular and having no bullion, can be cut with much less waste. In all glass some small air-bubbles are formed; in sheet glass, and in the forms of plate glass prepared from it, these small bubbles have an oval or elongated appearance, the result of the process of manufacture, whereas, in cast plate, hereafter to be described, the bubbles are perfectly globular.

Plate Glass. *Patent plate* glass, or *blown plate*, is produced by polishing sheet glass on both sides, and is generally formed of the thicker qualities. It is obtainable in two colours, ordinary *crystal* and *extra white*, and the qualities are known as *best*, "B," *second* or "C," and *third*, or "C.C."

Rough cast plate is the commonest form of plate, and can be obtained in sheets of large size; its thickness varies from $\frac{1}{4}$ in. to 1 in., and it is very strong, but the surface is somewhat wavy. It is used for forming the risers of steps, and for glazing windows near the ground level where protection is essential, and for pavement lights. It is the cheapest form of plate, and is made in one quality only.

Rough rolled plate was patented by Messrs. Hartley & Co., and is often known as Hartley's rolled plate. For this glass the iron table on which it is rolled has the surface covered with the fine lines or flutes formed on the surface, and these are impressed upon the glass when it is rolled out; the rollers are smooth, and one side only of the glass is thus fluted, but the other side is somewhat wavy. Glass can be obtained up to 10 ft. long and 3 ft. wide in this form, and it is rolled in the following thicknesses: $\frac{1}{8}$ in., weighing about 32 oz. per square ft.; 3-16 in., $\frac{1}{4}$ in., $\frac{3}{8}$ in. This glass is much used for skylights, conservatories, and in windows of factories, etc. Light admitted through it is somewhat diffused, and the glare of sunlight is diminished, but more light is obstructed by this quality of glass than by polished glass. In fixing, the smooth face is usually placed outside.

British polished plate is cast in the same way as rough cast plate, but a superior quality of glass is cast for polishing, and it is afterwards ground down to an even surface and then polished on both faces. This glass is prepared in several qualities—*silvering quality*, specially intended for mirrors, but used also for the highest quality of glazing; *best glazing*, and *ordinary glazing*. This glass can be obtained in sheets of immense size, though very large sheets are charged at a special rate but sheets up to 100 ft. area are usually kept in stock in several thicknesses. This glass is very clear and colourless, it transmits a greater proportion of light than any other material, and, in common with all forms of plate, is very strong; if $\frac{1}{4}$ in. thick, it prevents cold from penetrating to a great extent.

Figured Rolled Glass. There are various other methods of treating glass surfaces by rollers, which are of more recent introduction. But in all cases the method of production is somewhat similar. Of these forms of glass, one of the best known is *Muranese*, which is entirely covered on one face with small flutes, not parallel, but arranged somewhat after the pattern of a shell, in various shapes. This may be obtained in white or tinted glass. Another similar glass is known as *Arabesque*, and this also is formed with radiating grooves. Other forms are rolled, which are foliated in character, such as the *Japanese* pattern, in which flowers and foliage are represented on a ground covered with dots in place of grooves, and the *Flannel Flower*

pattern, which differs in design, but resembles the Japanese in treatment. The object of all these forms of glazing is to destroy the transparency of the glass with as little damage as possible to its translucence.

Wired Glass. This is ordinary glass, but has imbedded in its thickness a layer of wire netting. The glass surface may be treated either as cast or rolled or polished. The special advantage of the wire is that, in the event of the glass being broken by accident or by fire, the fragments are bound together by the netting, and will not fall out. It further increases the resistance of such glass to the attacks of burglars. The wirework is, of course, visible, especially in the polished glass, and this may make it undesirable to use for such positions as shop fronts, but for skylights, and in other positions in which the presence of the wire is not objectionable, it is very serviceable. It may be obtained in lengths up to 100 in., and up to 36 in. broad.

Glass ventilators are sometimes used; these may either be cast with perforations in them or the perforations may be cut afterwards. This is the most satisfactory plan, as such a ventilator can be cut where desired in a large plate; a circular disc of glass, with similar perforations, may be fixed over it so that it will rotate on its axis and form a hit-and-miss ventilator [**31**].

Cut Glass. Plate glass may be ornamented by cutting the surface so as to form a floral or foliated design. This cutting includes bevelling the edge, which is sometimes introduced and is effective, and also ornamental lettering. The surface is cut by means of an emery wheel, and afterwards polished. The wheel revolves on a stationary bed, and the glass must be brought into contact with it whenever any cutting is required. In order to do this, the sheet of glass is mounted in a frame and balanced with a counterpoise; it is then moved by the workman so that the cut is made of the desired size and shape. The cost of cutting is higher for the same amount of work on a large pane than on a small one, owing to the increased difficulty of manipulation.

French embossing is also executed on plate glass; in this work, the surface of the glass, excepting those portions which are to be embossed, is covered with Brunswick black; the surface is then subjected to the action of fluoric acid, which eats away the unprotected surface, giving it a dull, slightly opaque effect. The action of the acid may be stopped in certain parts of the design at any time by painting them out, and in this way some portions are more deeply eaten than others, affording a further contrast with the plain glass. The effect may be still further heightened by combining embossing and brilliant cutting in the same piece of glass.

Transparency of Glass. Even the most transparent glass will not allow all the rays of light that reach the external surface to pass through it, but some kinds of glass obscure or reflect much more light than others. The diminution of light caused by filling an opening with different qualities of glass, as compared with the same opening unglazed, is as follows: Of the total light received, British polished plate, $\frac{1}{4}$ in. thick, intercepts 13 per cent.; sheet glass, 32 oz. to the foot, intercepts 22 per cent.; rough cast plate intercepts 30 per cent.; rolled plate, four flutes to an inch, intercepts 53 per cent.

Glass is prepared in the special forms of *prisms* for certain glazing work; these are cast of the required form, and afterwards polished and made up into lights for use as pavement lights, stall boards, coal plates, etc. [**30**]. The manufacture of these lights is in the hands of special makers, and they are usually supplied complete in their frames, which in some cases, on account of their weight, are hinged and balanced with counterweights, if they are likely to be frequently opened. The object of all such prismatic glass is to deflect the rays of light reaching the inner face of the glass and to send the rays in a horizontal direction, or nearly so; by this means the back portion of rooms that would otherwise be very badly lighted may receive a greatly improved illumination.

Glazing with Putty. For most glazing fixed in wood or iron frames, *putty* is used for fixing the glass to the frame. *Glaziers' putty* is made of whiting mixed with linseed oil and well kneaded; sometimes a little tallow or non-drying oil is added to it to keep it slightly soft, so that it shall not be damaged by the alternate expansion and contraction of the glass. When used, the putty is in a plastic condition, but somewhat stiff; the frame should have been at least primed; and if this has not been done, the rebate that receives the glass must be painted, or the wood will soak up the oil in the putty before it had hardened. The glass is cut so as to fit somewhat loosely in the frame that is to receive it. If it were tight at any point, there would be a risk that the glass would split under the effect of expansion and contraction—if any slight settlement in the building should tend to alter the shape of the frame the same accident might occur—whereas, if it is slightly smaller than the frame, the conditions suggested should produce no such result. The edges of plate glass should be blackened before glazing, to prevent the effect of reflection from them.

Puttying. The first operation is to draw or spread a thin layer of putty fairly evenly along the back of the rebate all round the frame; this is not carefully smoothed, but left from the knife that is used to spread the putty. The sheet of glass is placed in the frame and pressed firmly against the putty on the rebate, which thus becomes reduced to a uniform thickness, and some putty is generally squeezed out in the process and will stand above the wood of the sash all round on the inside of the glass. This is not at once removed, but left till it gets hard, and is then cut off, generally after an interval of about a week.

If the sheet of glass is large and heavy, it is very often *sprigged*. This consists in driving small brads of iron or brass into the woodwork at intervals, to hold the glass in position till the putty has hardened and is firm enough to hold the glass securely. But with panes of ordinary size this process may be, as a rule, omitted. When the glass is in position, additional putty is worked on all round the panes on the outside, and finished with a sloping or weathered surface [**32**]. The external surface of the putty should be painted at once, to prevent its drying too rapidly and cracking. A sash tool [**11**] is used, and care must be taken to see that the paint is not smeared on the glass.

Putty Glazing to Skylights. When putty is used for glazing skylights, the system is similar. It is desirable, when possible, to employ a single sheet of glass to glaze each division of the light. The lower edge, or *tail*, is often supported by a copper clip [**40**] to give it additional security; and if two or more sheets of glass are used, they must be well lapped, and a copper clip may be used to support the upper piece. The extent of lapping will depend on the slope, but is usually about

1½ in. The lower edge of the glass runs over the apron of the light, and should be allowed to cover it completely; but in some cases it is stopped on the back of the apron, with the result that water is delivered on to the surface of the apron, and, especially if the inclination of the light is not great, this is liable to rot the wood. In glazing greenhouses and garden-lights, the glass used is generally thin, and is used in small pieces, with several horizontal joints and a small lap. In such work the metal clips above referred to are not required. If ground glass is to be fixed with putty, the surface round the edges should first be sized to prevent the putty from discolouring it.

Glazing in Stone and Terra-cotta. In certain styles of buildings sheets of glass which are not required to open may be fixed in the stone or terra-cotta opening without the use of any wood or metal frame. This is usually done by forming a rebate in the frame, fixing the glass against the rebate, and securing it in position with hardwood beads or mouldings screwed to wood or lead plugs let into the jambs [**33**]. The outer edge between the glass and the rebate is pointed all round in cement.

Where the glass does not consist of a single sheet, but is in the form of a leaded light, a groove is formed instead of a rebate in the material of the window opening, and the glass-light can be slightly bent, placed in the groove, and afterwards straightened out and fixed and pointed in cement [**34**].

Saddle bars are usually required for assisting to support lead lights which, in windows of any size, are not rigid enough to resist any considerable wind pressure. In the simplest form the saddle bar is a square bar of iron from ⅜ in. square upwards, depending on the strength required. The ends are fixed to the frame into which the light is fixed, and the light is secured to the saddle bars with copper wire [**35**]. If the jambs of the opening are of stone or terra-cotta, a mortise is cut in each side for the saddle bar, and it is run in with cement. If a wood frame is used, the ends of the bar may be turned up and flattened and perforated for a screw and then fixed to the frame.

Glazing Internal Lights. Where glass is to be fixed in an internal screen or door, putty may still be used; but in such cases, when there is no exposure to the weather, it is not essential—and it is often preferred—that both sides of a frame should have the same character and appearance. In such cases the glass may be secured in the rebate by means of small wood beads or mouldings fixed to the frame and glazing bars with small screws [**36**]. These should be of brass, and brass cups are usually provided and let into the beads to take the heads of the screws exactly. Such an arrangement allows of easy and quick repair to any pane that has been broken, by merely removing the mouldings, inserting the new pane, and refixing them. Where the upper panels of doors have to be glazed, the same system may be used, but a strip of washleather or vulcanised indiarubber is used for holding the edge of the glass, to reduce the vibration due to the opening and closing of the door, which might otherwise crack the glass.

Glazing Without Putty. The drawbacks of putty are that the material does not remain permanently sound, but is apt to perish, especially in the case of skylights in which the glass is not placed vertically, but often at a very flat angle. This decay may be greatly retarded by careful painting at least in every second year, but in time putty is apt to crack, and ceases to be watertight. Several systems have been adopted to avoid the use of any putty, and to provide for securing the glass in position by mechanical means. Such a system must be, nevertheless, watertight; must not interfere with the expansion or contraction of the glass, and at the same time must render the execution of repairs an easy and rapid operation. It is essential that the construction be strong enough to allow of workmen getting about on the roof to execute repairs. The simplest form of this class of glazing is termed the *Simplex* [**37**], and can be utilised with existing wood lights and bars by removing the rebates on the latter, or may in new work have bars specially prepared for it. The system makes use of a strip of lead specially folded so that it may be nailed to the top of the bar, and, after the glass is put into position, the edges are turned down and dressed over the glass. The lead strips are secured to the wood bars with copper nails, placed on alternate sides of the centre line 4 in. apart.

Rendle's Invincible glazing [**39**] has a specially formed bar of zinc or copper provided with condensation gutters, which is sufficiently strong for lengths under 4 ft., but for longer lengths must be carried on a bar of wood or a T-iron. The glass rests on this bar, and a metal capping is employed, secured by bolts and nuts at intervals.

Hope's glazing has a specially moulded steel bar with a dovetailed groove in the centre of the top. Into this a special cast-lead cover strip is screwed, with flanges dressed down over the glass.

Helliwell's Perfection glazing [**38**] also employs a moulded steel glazing bar, with a capping of lead, zinc, or copper fixed with brass bolts and nuts.

Leaded Lights. *Leaded lights* are formed of small pieces of glass fitted into grooved lead strips, which are soldered together to form lights or panels. The glass may be white, coloured, stained, muffled, or rolled. The lead strips, or *cames*, are of an H section and are drawn, and the joints are soldered. The cames are cut rather short, and drawn through a *compression vice*, the effect of which is to harden and polish the surface and to mill the groove. The centre between the grooves is the *heart*, and each of the sides is termed the *leaf*. This is usually flat or round, but may be beaded, and is, for ordinary glazing, from ¼ in. to ½ in. wide, but may be as much as 1 in. The two leafs are opened out to receive the glass, and then a cement is brushed under the leaf, consisting of mastic or whiting and red lead, and the leaves are then closed down on the glass and coated with blacklead, or the surface may be gilded. They should be allowed a week to harden before fixing. The cames are bent to fit the outline of irregular pieces of glass, and the various lengths of cames are soldered together where they meet. Short lengths of copper wire are also soldered in for fixing to the saddle bars already referred to. The cames often play an important part in the design of ornamental lights; and in all such work due provision for the saddle and stay bars must be made.

A more rigid method of fixing up panels from small sheets of glass has been, within recent years, introduced by the Luxfer Company. The pieces of glass are carefully cut and laid out on a table with copper ribbons till the panel is formed up of the requisite size. This is then put into an electrolytic bath, and copper is deposited between the edges of the glass, and intimately connects it with the frame, forming an extremely rigid panel.

Erecting Poles and Running the Wires. Insulators. Wire Tables. Ohm-mile Constant. Underground Pipe-laying. Cabling and Jointing.

POLE, WIRE, & UNDERGROUND WORK

Aerial Lines. Great skill and judgment have to be brought to bear on the construction of aerial telegraph and telephone lines. When a conductor suitable from the point of view of resistance and mechanical strength has been chosen, there remains the mechanical problem of supporting and insulating the conductors at a suitable height to secure freedom from interference, and with sufficient strength to meet the static stresses due to the weight of materials and the kinetic stress due to the wind pressure.

The static stress is greatest at the pole where the line begins or ends, usually called the *terminal pole*. There it is the sum of the stresses of the wires; at intermediate poles, where the line is straight, the static stresses due to the wires on each side may balance each other, and in this case the pole, together with half of the span of wires on each side of it, may be considered as analogous to the mast and sail of a ship; the wind presses on the side of the wires as on the side of the sail; and if the pole is not sufficiently strong it will snap off at the bottom, as does many a good mast. For this simplest case, then, we need to know something about wind pressure.

Wind Pressure. Wind pressure varies as the square of the velocity. A brisk wind of 20 miles an hour exerts a pressure of 1·08 lb. per square foot; a very high wind of 40 miles per hour gives 4·32 lb. per square foot; 70 miles an hour gives over 17 lb. per square foot; while a hurricane may attain a velocity of 100 miles per hour and a pressure of over 32 lb. per square foot. Standard practice has decided that lines should be built to resist a maximum pressure of 17 lb. per square foot.

Next, we must ascertain the dimensions of the resisting surface. As the wires are circular, the effective area is taken as two-thirds of the diameter into the length. A simple calculation will therefore give the horizontal stress due to wind pressure. But this is at the height of the wires. To find the moment at the ground line, we must multiply by the distance between the resultant point of the pressure—usually midway between the top and the bottom wires—and the ground line. The result is usually expressed in foot-cwts. This tells us, then, the stress which will act upon our pole at the ground line. The engineer is provided with a table in which the breaking stress in cwts. for various thicknesses of poles is recorded, and he might now obtain from this list the dimensions of a pole which would give the required strength. Where wooden poles are concerned, however, the possibility of a particular sample being much below the average has to be borne in mind, and in this case, as in all similar engineering designs, it is necessary to introduce a factor which shall make for safety, and is, indeed, always referred to as the *factor of safety*. For poles and supports this factor is taken as 8; so that, before selecting from his list, the engineer would multiply the "foot-cwts." result by 8. For poles at angle points allowance must be made for the increased static stress.

Selection of Route. The erection of a line is preceded by careful surveys, in which the relative advantages of different routes are considered, and the one is chosen which combines most of the following advantages:

Shortness, so as to reduce the cost;
Straight rather than tortuous roads;
Ease of access for building and maintenance:
And freedom from difficulties as to wayleaves.

During the progress of the detailed survey all information for the guidance of the foreman who will erect the line is carefully tabulated, positions being chosen for the poles so as to avoid causing obstruction to the public and danger from passing vehicles. They must also be chosen so that the wires shall not hang longitudinally over the carriageway, and poles should be placed so that, if the wires fall, they will fall clear of traffic. Road crossings should, as far as possible, be avoided, and on hilly roads the heights of the poles are adjusted, as far as possible, so as to avoid abrupt differences in the level of the wires.

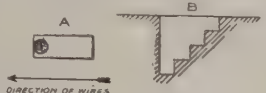
Poles. Wooden poles are used almost exclusively in this country. Wooden poles are preserved from rot by creosoting; 6 lb. of creosote per cubic foot is injected into the pole. Poles so treated have very long lives. They can now be painted, the Ruping process, recently adapted, enabling this to be done. Cresosoted poles having lengths up to 85 ft. and diameters up to 20 in. can be obtained. For light lines the poles are placed at 70 yard to 80 yard intervals, and for medium and heavy lines 66 yards is the usual interval.

Hole Digging. The hole for the pole should be dug in the direction of the wires. As little ground as possible should be disturbed. It should be arranged so that the pole will stand at one end, and this end should be cut down perpendicularly [39]. For ordinary lengths 4 ft. to 6 ft. is the usual depth, but the character of the soil must be taken into consideration. For very long poles 8 ft. to 10 ft. may be necessary, but this is the maximum. In very loose soil or running sand it is sometimes necessary to use concrete. The poles should be set so as to bear against the stress of the wires. In returning the earth to the hole, great care must be taken that the soil is thoroughly punned in, and on completion the soil of the roadway should be returned, as far as possible, to its original condition.

The height of the pole should be such that along country roads the lowest wire is not less than 12 ft. from the ground; in crossing roads and railways this must be increased to 20 ft.; in towns, 22 ft. minimum for road crossing and 28 ft. for crossing overhead trolley wires.

Iron poles are made of 11 ft. parallel lengths with 16 ft. tapering lengths, and the bottom fits into a cast-iron base, which gives a good hold in soft ground. A concrete foundation is usually provided, so that the pole may be secured by bolts let into the concrete. The parts of the pole are put together on the ground.

Stays. The strength of a line is enormously increased by a proper discrimination in providing stays at suitable points. Stays are usually made of iron wire, and they are arranged so that the upper end is attached as nearly as possible at the resultant point where all the forces acting upon the pole can be balanced by an opposing force. They are therefore specially suitable at angle points. The lower end of the stay is connected to an iron rod fitted with a stay tightener, and the farther end of this rod is passed through a wooden block, usually a 2-ft. length of old pole. The hole for the stay block is usually arranged so that the block is placed in an under-cut space and fits against the solid earth. Where it is impracticable to fix stays—as, for instance, at an angle in the road where the stay would have to be put on the road side of the pole—struts are used, and figure **40** sufficiently illustrates their application.



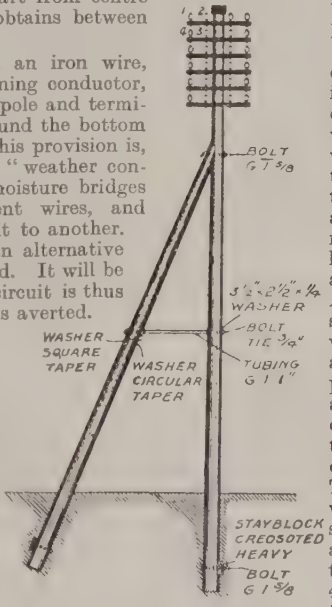
39. HOLE FOR POLE

For the heaviest class of trunk telephone lines, the Post Office has within the last few years introduced a system of trussed "H" poles. These have given splendid results and are illustrated in diagram **41**.

Pole Arms and Fittings. For arms, British oak, well seasoned, is usually employed, and sometimes kauri wood. The sections vary from 2¼ in. to 3 in. square. Arms 48 in. long carry four insulators, and lengths up to 78 in. are in common use. Arms are usually spaced 12 in. apart from centre to centre, and this distance also obtains between the respective insulators.

Poles are always provided with an iron wire, which is arranged to act as a lightning conductor, and is stapled down the side of the pole and terminated in one or two coils stapled round the bottom of the butt. The main purpose of this provision is, however, to prevent what is called "weather contact." In wet weather a film of moisture bridges the distance between the adjacent wires, and current would leak from one circuit to another. The *earth-wire* provides, however, an alternative path. The arms are also earth-wired. It will be seen that the loss of current per circuit is thus slightly increased, but interference is averted.

Pole Roof. The top of the pole is usually cut obliquely, coated with a mixture of coal-tar, creosoted and provided with a galvanised iron roof. In towns, ornamental pole-finials are used. When the fitting of the pole with roof, earth-wire, arms, and, in some cases, galvanised iron steps, has been completed, it is erected by pushing the butt into the hole, so that the butt end will come easily into the place it will finally occupy. The stepped end of the hole acts as a fulcrum in such a way that the weight of the butt assists in lifting the top, and the pole is gradually raised to the vertical position at first by hand, and subsequently by ladders, half a dozen men being usually employed. Even for the heaviest poles, ten men are quite sufficient where the foreman exhibits proper generalship. The presence of too many men is apt to be a source of danger, and a proper understanding between those concerned in the work is of the utmost importance.



40. POLE WITH STRUT

Insulators. The standard pattern insulator used in England is made of white porcelain, screwed so as to fit on a screwed steel spindle, and provided with two petticoats [42]. For short lines, where a very high standard of insulation is not necessary, brown earthenware made in the same pattern is frequently used. In fixing the insulator an india-rubber washer is inserted between it and the shoulder of the spindle to allow for differential expansion. The insulators are put into position after the pole has been erected, the steel spindles being securely bolted to the arms. It is interesting to note that in America glass insulators are used instead of porcelain, and wooden (locust) pins instead of steel spindles. At terminal poles, where the pull is all on one side, J-shaped spindles are used, fixed to the under side of the pole, and arranged so that the pull of the wire comes opposite the centre of the arm—this prevents the arm from being twisted.

Wire. Three classes of conductor are in general use—namely, iron, copper, and bronze—iron wire for unimportant telegraph circuits, copper for important telegraph and telephone circuits, and bronze wire for use in towns where irregular spans demand increased mechanical strength. Full particulars are given in the table.

Ohm-mile Constant. This should be carefully memorised. It enables the resistance per mile of any conductor, which may be named by its weight per mile, to be at once ascertained.

Thus, if 70 lb. bronze is referred to, $\frac{1820}{70} = 26$, which is the resistance in ohms per mile. See table on page 5504.

Erection of Wire. The effects of temperature have a most important bearing upon the erection of aerial wires. It is clear that, if wires are erected in hot summer weather, when winter approaches they will gradually shorten, owing to the decrease in temperature, and if sufficient allowance is not made for this it is possible that the limit of elasticity may be passed and the wires ultimately broken. Arrangements are therefore made so that the stress to which the wires are pulled up on erection is arranged with reference to the temperature in such a way that should a winter temperature of 22° F. occur, the stress will then be at the maximum allowed—namely, one-fourth of the breaking stress. This is another way of saying that wires are erected with a factor of safety of 4 for low winter temperature, and that at all other times the factor of safety is higher than 4. To secure this state of affairs, tables showing the stresses for various lengths of span corresponding to different temperatures are prepared for all classes of conductors, and supplied to the wiremen, who are also supplied with thermometers. Owing to their differing temperature co-efficients, dissimilar conductors are never erected on the same pole route if it can be avoided. For bronze, a factor of safety of 3 instead of 4 is employed.

Twisted Wires. For the purpose of eliminating inductive disturbance in metallic

telephone circuits, it is necessary to arrange the two wires which form a loop in such a way that their average distance from all disturbance is the same. This condition is attained in England by causing the wires to revolve round each other. Four wires forming two telephone circuits are taken together, and arranged so that they form a square on, say, the left side of the pole on the top two arms [40]. These are numbered as follows:

No. 1.—Top outside.
No. 2.—Top inside.
No. 3.—Bottom inside.
No. 4.—Bottom outside.

Nos. 1 and 3 form one circuit, and 2 and 4 the other circuit. At the next pole the wires from No. 1 position will shift to No. 2 position, the No. 2 wire to No. 3, and so on, and this process is continued, so that on the fifth pole the wires come back to the same position that they occupy on the first, having completed one revolution. If, now, a single-wire telegraph circuit is sending out disturbing electromagnetic waves, the inductive effect on one wire of the telephone circuit will be balanced by the equal and opposite effect of the other, and the disturbance will be completely eliminated. In American practice it is preferred to run the wires straight on the arms, introducing, however, crosses at frequent intervals on what are known as "transposition poles."

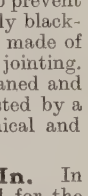
41. POLE FOR HEAVY TRUNK LINES

Joints. The connections between successive lengths of iron wire are made by means of the Britannia joint. The ends of the two lengths of wire are cut off and laid side by side for about 2 in.; binding wire is then wrapped round the conductors over the whole of the over-lap portions, and with a few turns on the single conductor at each end; and 60 lb. galvanised iron is used for jointing. A flux is then applied, and the joint rapidly soldered, overheating being carefully avoided and the joint being allowed to cool naturally. In order to prevent electrolytic action, the joint is subsequently black-varnished. For copper conductors, sleeves made of flattened soft copper are employed for jointing. The ends of the wires to be jointed are cleaned and slipped into the sleeve, which is then twisted by a special tool, thus making a good mechanical and electrical joint without soldering.

Wire Running and Binding In. In order to pay out the wire uniformly, and for the purpose of avoiding kinks, a rotating drum is employed. A long length of wire is run out, sufficient for eight or ten spans, the wiremen passing it out loosely over the arms at each pole. The wires are first drawn up as tightly as possible by hand, and then by draw-tongs. A tension racket is connected to the draw-tongs for the purpose of observing the stress. When the wires have been drawn up to the proper tension they are attached to the insulator. This is done, in the case of iron wire, by using 60 lb. binding wire. This is first lapped round the line wire on one side of the insulator, then taken round the neck of the insulator and lapped round on the other side; two thicknesses of wire are usually employed. For copper wire, a different method is in vogue: the line wire is first served with a sheath of copper tape to protect it from abrasion against the insulator neck; a copper binder, about 20 in. long and having its centre of round copper and its ends flattened out, is then applied; the round part passes round the insulator neck, and the flattened ends are wrapped round the taped conductor, the wrapping being arranged over on one side and under on the other. The effects of the mechanical stresses are most violent at the point of the attachment to the insulator, and this is where breakages most usually occur.



42. INSULATOR

Maintenance of Aerial Wires. Skill and judgment are as necessary for the maintenance as for the erection of lines such as have been described, and in stormy districts the lives of the engineers and linemen are seldom troubled by monotony. As the number of wires increases, constant vigilance has to be exercised, to eliminate weak spots. The poles have to be examined periodically to see that the normal factor of safety has not been unduly encroached upon. In districts where snow prevails, accumulations sometimes take place which transform the wires into white ropes of 3 in. to 4 in. diameter, a result which is usually followed by the practical demolition of the lines, especially where frost and wind follow the accumulations. Trees are often blown by the wind across the lines, and when one span has been broken through the trouble may run back for a considerable distance, owing to the sudden removal of the balancing stresses. Spans over rivers and ravines have to be negotiated, and in all cases the work of repair has to be done against time, as communication must be restored after the briefest interval.

Underground Work. Aerial conductors have, broadly speaking, two principal advantages over the underground method of construction—namely, low cost and, owing to the small electrostatic capacity, high efficiency as electrical con-

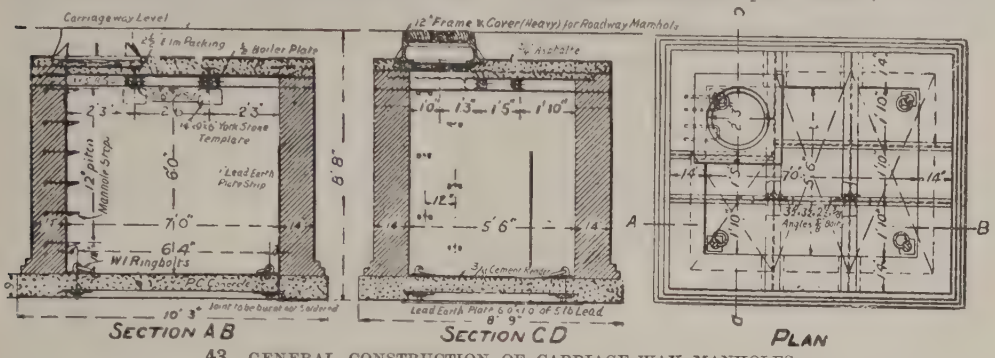
ductors, but these are frequently outweighed by other factors, which lead to the substitution of subterranean routes.

In large cities, overhead routes are generally unobtainable. Moreover, when some degree of conducting efficiency can be sacrificed, and where the number of conductors is large, the underground system may be found to be cheaper, especially when



43. GENERAL CONSTRUCTION OF CARRIAGE-WAY MANHOLES

the cost of subsequent maintenance is taken into account. Maintenance, which is heavy in the case of aerial wires, may, by good first construction, be reduced to insignificant dimensions in the case of underground work. Until about the end of the last century, wires insulated by a covering of gutta-percha were almost invariably used. These were placed in iron pipes of 2 in. or 3 in. diameter, with joint boxes at suitable intervals. When telephone circuits were concerned, the wires were made up in fours, twisted together to form a "quad" cable. A 2-in. pipe could take seven and a 3-in. pipe nineteen of such quad cables; and as they could not be drawn in over each other, it was necessary either to fill the pipe at one operation, or, in cases where this had not been done, to draw out one lot before pulling in another.

These G.P. wires had conductors of 40 lb. copper, insulated with 50 lb. of gutta-percha to a diameter of 174 mils (the mil is $\frac{1}{1000}$ in.), and not more than eighty wires were ever pulled into a 3-in. pipe.

Cables. The invention of the dry-core cable has, however, revolutionised affairs, and it is safe to say that the present highly developed underground telephone systems would have been impossible without it. In this form of cable the wires are wrapped in paper, but the real insulator is dry air. The electrostatic capacity is one-fourth that of gutta-percha cables. The paper-covered wires are enclosed in a tube of lead, but the economy of space is such that a 3-in. iron pipe will accommodate any of the following lead-covered cables:

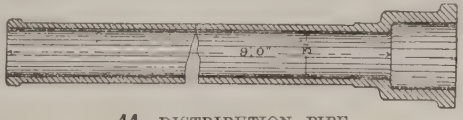
100	*pairs*	with 40 lb.	conductors
300	„	„ 20 lb.	„
800	„	„ 10 lb.	„
1000	„	„ 6½ lb.	„

as compared with the eighty gutta-percha-covered wires already mentioned.

Post Office London Underground System. It is probable that a description of the methods adopted by the Post Office in laying down their huge underground system will best enable the student to comprehend this subject. Beginning at the exchange, we have first the main conduit routes. These are laid along the centre of the main thoroughfares, and contain ducts varying from six up to any required number.

Earthenware Ducts. The ducts are made of earthenware, 18 in. and 24 in. in length, with internal circular section $3\frac{1}{4}$ in. diameter, and external hexagonal section $4\frac{1}{2}$ in. diameter. In building a duct route, the ground is first excavated, and, if necessary, shored up. A 6-in. concrete foundation is then laid, having embedded in it T-irons laid lengthwise under every alternate line of ducts. These are $2\frac{1}{2}$ in. by $2\frac{1}{2}$ in. by $\frac{1}{4}$ in. thick, and they are employed to resist the vertical displacement stress. When the concrete has set, the layers of ducts are put down, bedded in cement mortar. As in the case of succeeding lines of brickwork, the ducts are arranged so that the joints in one line do not coincide with those in adjacent lines.

To facilitate jointing, wooden mandrels are used, 11 in. long and $3\frac{1}{8}$ in. diameter. When a joint is being made, the mandrel is arranged so that one half of it is in each of the abutting ducts. A strip of prepared calico, which has been soaked in ozokerit to make it adhesive, and which is 20 in. long by $4\frac{1}{2}$ in. wide, is then wrapped tightly round the joint. The mandrel is then drawn forward. Such joints can be made rapidly, and a train of a dozen mandrels is usually employed. Of course, it is absolutely essential that the ducts shall not be deflected during the subsequent operations, and, once the cement mortar has set, the permanence of the whole system is assured. When all the ducts required are in position, concrete is added to the sides and top, and the roadway filled in and reinstated.



44. DISTRIBUTION PIPE

Multiple Way Ducts. An alternative method of providing conduits is in the form of concrete blocks, called *multiple way ducts*. These occupy less space and are cheaper, and, wherever a straight route is available, are now used in preference to the built *in situ* system which we have described above.

The blocks are made in sizes for 3, 6, 9, 12, 16, 20, 25, 30, and 36 ducts. They are all one uniform length—one metre (39·37 in.). In laying them, the joints rest on short concrete bearers bedded in the earth, and strength and proper alignment are secured by continuous lengths of square iron rods, which are inserted in recesses in the top and sides of the blocks. The iron rods are covered with cement.

Manholes. At intervals of 150 yd. to 180 yd. manholes are provided to house the joints. If possible, the junction of thoroughfares is chosen as the position. These roadway manholes have to be of substantial construction, a need which is emphasised in these days of heavy motor traffic. The minimum dimensions are: length 4 ft., width 4 ft., height 4 ft. 6 in., and these are increased as required, a very common type being 8 ft. by 7 ft. by 5 ft. 6 in. The method of construction may be briefly described as follows.

The trench is widened and deepened, and a 6-in. floor of concrete laid down, but with the thickness at the sides extended downwards to 9 in. to form footings for the walls, which are of 14-in. brickwork. An earthplate of 5-lb. lead, 6 ft. long by 1 ft. broad, is laid under the concrete, to be subsequently connected to every cable sheath by a 1-in. strip of lead, which is taken up the inner wall of the manhole. Provision is also made for the subsequent drawing-in operations by embedding in the concrete in each corner heavy wrought-iron ring-bolts, with large anchor plates bolted on below the concrete. When the concrete has set, the walls are built. Galvanised iron footsteps are built into the corner, above which the entrance is to be placed, and when nearing the roof-line the stone templates which form the supports for the roof joists are carefully set in position. The roof is as simple in construction as it is strong. The width of the manhole is bridged by rolled steel joists of 8 in. by 6 in. section. These, in turn, are connected together, and to the walls at each side, by smaller rolled steel joists (4 in. by 3 in.). Resting on these is placed a roofing of ½-in. boiler-plate. Above this comes 6 in. of concrete, and then a layer of asphalt. Above this the road is made up in the ordinary way, except at the entrance corner. Here a heavy cast-iron frame, 12 in. deep, is provided, into which fits a similar lid, having its upper surface filled in with wood blocks set in pitch. The inner walls of the manholes are carefully pointed, and the floor covered with a ¾-in. rendering of Portland cement. Fig. **43** gives details of a typical manhole.

Distribution Pipes. While it is necessary to have the main routes in the roadway, the distribution pipes must be as near to the shops and houses as possible, and they are therefore run along the footpaths. For this purpose, cast-iron pipes are used. These are classified, according to their internal diameters, as 2-in., 3-in., or 4-in. The first-named are made in 6-ft. lengths, the others in 9-ft. lengths, and the respective weights are 42 lb., 98 lb., and 154 lb. A 3-in. pipe placed on supports 5 ft. apart will support a ton and a half, and a jointed pipe, similarly tested will support a load exceeding a ton. They are coated with Dr. Angus Smith's composition, which prevents rusting and gives a glazed surface. Fig. **44** illustrates such a pipe. The left end is called the spigot end, and the right end the socket end. Bends of convenient dimensions are also provided.

In laying a line of distribution pipes, great care has to be exercised in the choice of the route. Allowance must be made for existing gas, sewer, electricity, hydraulic, and other mains, and in many cases the existence of under-footway coal-cellars makes special difficulties. Very often the line nearest the house-line is found to be the best, because not only is it most economical for distribution, but, owing to the fall of the paving to the roadway, the distance from cellar top to paving is here at a maximum. Ten men form a convenient gang; and when the foreman has chalked out the route, the paving is taken up, great care being exercised to avoid breakages, and the stones (where York or artificial stone is concerned) being laid so as to enable them to be returned to their original positions. While the first dozen yards of trench are being excavated, the jointing of three lengths of pipe is in progress. For this purpose four blocks of wood, with V-slots in them, are set up at (for 3-in. pipes) distances of about 9 ft. The spigot end of the second pipe is fitted into the socket of the first, and so on with the third; but before being brought together they are carefully gauged and examined to see that their interior surfaces are in order.

Into the annular space between the spigot and socket a length of spunyarn is inserted, being first wrapped round the spigot and then driven home by a caulking iron. Meantime, a roll of clay has been prepared by wetting and rolling on a board, and this is placed under the pipe and round the mouth of the socket, the ends being brought up above and curved outwards, so as to leave an opening into which molten lead may be poured. The space between the yarn and the clay is in this way filled with lead, which efficiently joints the two lengths of pipe. The clay is then removed, to be used again, and the cooled lead tightly caulked. A level bed having been prepared in the trench, small holes are made to receive the sockets, and the pipes are lowered into position. One joint in every four has to be made in the trench. A No. 8 iron wire is threaded through the pipes length by length as they are laid, to be used in the drawing in of the cable.

Under fair average conditions, a good gang can lay 100 yd. in a day of 9½ hours. Footway jointing-chambers of various sizes are provided at intervals not exceeding 100 yd., but they are usually required at more frequent intervals for distribution purposes. Six sizes are in use, varying from "double junction" boxes, 4 ft. 2 in. by 1 ft. 11 in., down to "distribution" boxes, 1 ft. 2 in. by 8 in. A concrete floor with Portland cement rendering is provided, and the sides built up of brick, the box proper being merely an iron frame designed to hold the iron lid, the top of which is filled in with stone. The connection between the footway boxes and the subscribers' premises is made by a length of 1 in. pipe. The connection between the roadway manhole and each of the adjacent footway junction boxes is in all cases made by three lengths of pipe.

Cable System. Having disposed of the pipes, we may now consider the cables more fully. It has already been mentioned that a short length of silk and cotton insulated cable connects the street cable to the main frame. This is for convenience of handling. The silk and cotton cable is made solid in the process of manufacture by filling it with beeswax.

The main distribution cables are varied in type, according to the purpose in view.

For serving subscribers near at hand, cables containing 1000 pairs of 6½-lb. conductor are used; for the next ring, 800 pairs of 10 lb. conductor, while for the outer ring cables of 300 pair, 20 lb. are available, the heavier conductor being necessary to provide for transmission requirements.

From the exchange basement the main cable runs through the ducts to the point where the main route is branched into two or three subsidiary routes by means of a Y or multiple joint. For instance, a twelve-hundred-pair cable may be connected to two six-hundred-pair cables or three four-hundred pairs. The whole joint is enclosed in lead, and sealed up by plumbers' wiped joints;

and to reduce the possibility of disturbance to a minimum, provision is made in advance for the anticipated development of the forthcoming eight years.

Main Cabling. The drawing in of the cables is known as *cabling*. In the case of main routes, it is first necessary to *rod* the pipes. Sweeps' rods, with patent trigger joints, which prevent unscrewing in the pipes, are jointed length by length and pushed through the ducts. They are then used to pull through (*a*) a spun yarn mop, (*b*) a circular brush, (*c*) a test piece of cable one yard in length, and (*d*) a 3-in. rope. (*a*) and (*b*) are used to clean the duct, (*c*) is examined to see if any obstruction may be anticipated, and (*d*) is to be used for drawing in the cable. The cable, which is mounted on a big wooden drum, may weigh from two to three tons, and is brought to the manhole on a low float. To enable the drum to be revolved, a steel axle is passed through its centre, and it is elevated on a pair of screw jacks. At the other manhole a winch has meanwhile been got into position, and the pulley rope brought round a pulley block anchored so as to be opposite the proper duct when the strain is applied. When all is in readiness, four men turn the winch handles and the cable is fed in, turning off the drum and through a large arc of a circle into the duct. A liberal dressing of petroleum jelly is applied in order to facilitate its progress [45].

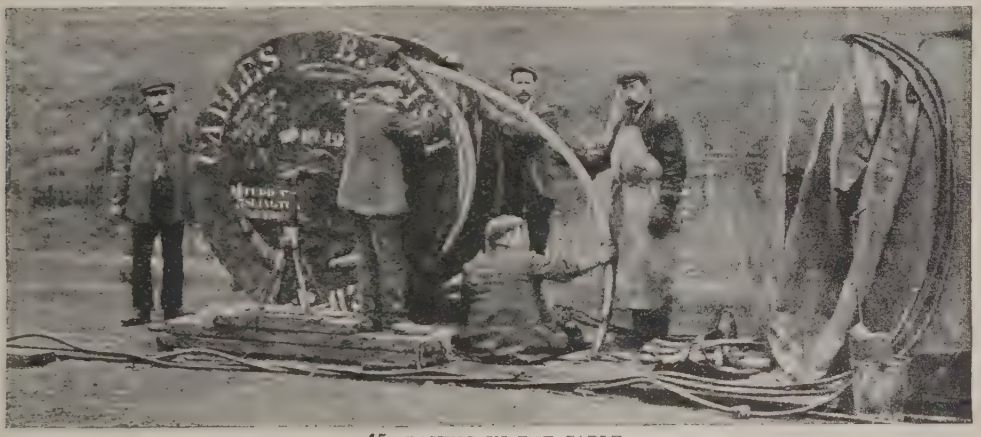
Motor winches have displaced manual labour to a considerable extent.

Similar operations, but on a smaller scale, are carried out in connection with the distribution cables.

Cable Jointing. Proceeding from the less to the greater, we will first describe the making of a joint between two lengths of seven-pair cable. The materials required are a lead sleeve, small paper sleeves for covering the conductor joints, some solder, some mixed resin and Russian tallow, lamp-cotton, thread, and wrapping paper. Everything must be kept properly clean and dry, and to this end a Gothic tent is usually mounted over the joint-box. The paper sleeves and wrapping paper are kept warm over a spirit-lamp. The lead sleeve is threaded on to one of the cables.

From each cable end a 6-in. length of lead is removed, exposing the outer paper wrapping, which is cut off back to the lead. The seven pairs of wires, each with its identifying coloured thread, are separated, in each case the thread being carefully looped round its proper pair. The arrangements for identification are so complete that when the jointing has been done properly a cable can be cut into at any point and any required wire picked out. To achieve this, the two wires forming a pair are wrapped one in red and one in white paper; these are the A and B wires respectively of the telephone pair. Round the centre pair of wires there is a white thread. This is No. 1 of the seven pairs. No. 2 has a black thread, No. 3 blue, No. 4 green, No. 5 two threads, one red and one black, No. 6 red and blue, and No. 7 red and green. Without unrolling the paper the whites of No. 1 pair are laid across each other at a point $1\frac{1}{2}$ in. from the ends, the white thread from one side being included. A few twists are made, and then the remainder of the paper is stripped off, and the copper conductors twisted together for a length of an inch. The twisted joint is then laid parallel with the wires, and a paper sleeve, which has previously been threaded on to one side, is brought over the copper joint. The other pairs are similarly treated, an expert jointer arranging that the joints are "staggered" so as to reduce the maximum diameter.

A wrapping of paper is then put over all, and tied down tightly with thread. The lead sleeve is now pulled over the conductors and set up vertically, so that one end may be soldered. A little wad of lamp-cotton is first pushed in between the cable and the sleeve, some tallow and resin come above this, and by means of a small spirit blow-lamp the opening is neatly closed with solder. The other side is similarly dealt with. It should be stated that before making such a joint the lengths of cable are adjusted, so that when completed the cable joint may be neatly trained round the box and fastened up along the side on a supporting bracket.



45. PAYING IN THE CABLE

Cable Codes. To facilitate reference and identification every cable has code letters allotted to it. Junction cables have four letters; main distribution cables, three letters.

The connecting up of subscribers takes place from the box outwards, and in a properly managed system plans are kept up to date, showing the position of every wire, both working and spare, and new subscribers are added without the slightest disturbance to those in existing cables, everything being planned out in the drawing-office, and complete detailed instructions issued to the workmen.

D. H. KENNEDY

Orchestration—continued. **Instruments in Combination. The String Band. The Full Orchestra and Theatre Band. Conducting and Choir Training.**

ORCHESTRAS AND CHOIRS

HAVING briefly described the instruments most generally in use in the modern orchestra, we may now consider the effect of them in combination.

The String Band. First in importance comes that group known as the string quartet, or string band. As has been already mentioned, this consists of a number of violins divided into firsts and seconds, a smaller number of violas, violoncellos, and double-basses. The relative numbers of these constituents vary considerably, but an ideal orchestra might contain 16 first violins, 16 second violins, 12 violas, 12 'cellos, 8 basses.

The beginner will perhaps be disposed to think that there is not much variety to be obtained from this one type of instrument, but a slight investigation of already existing music will speedily convince him to the contrary. Let us cull four examples at random, and note the immense contrasts of colour [Ex. 46–49].

In our first example, from Mendelssohn's overture to the "Midsummer Night's Dream," an effect of ethereal lightness is produced by the *pianissimo staccato* of the violins; the 'cello and bass, too heavy for this fairy music, are omitted altogether. Attention should be drawn to the fact that both the first and second violins are divided—that is, the violins are playing in four parts instead of two. This is a most valuable device in orchestral writing, and many composers have still further elaborated it by dividing certain sections of the strings into four, eight, twelve, or even sixteen parts; but it is doubtful whether the effect in performance justifies the labour entailed in the writing.

The device of dividing the 'cellos into four parts may be seen in our second example; the effect in performance is one of the most beautiful in the whole range of orchestration. In the third example is shown a solo for the violas and 'cellos in unison, with the basses accompanying pizzicato. Lastly, the strings are shown in a polyphonic movement—a word meaning, literally, many-sounding, but used synonymously with contrapuntal.

This is but a small selection of the different effects that can be produced by the strings alone. Before proceeding further, the student is recommended to take a selection of simple piano pieces and score them for string orchestra. The following suggestions may be helpful:

Beethoven. Sonata Op. 2, No. 2. (Slow movement.)
Beethoven. Moonlight Sonata. (2nd movement.)
Schumann. Papillons. Op. 2. Nos. 1, 3, 4, 5, 8, 12.
Schumann. Kinderscenen. (A selection)
Grieg. Lyric Pieces. (A suitable selection)
Schubert. Theme from Impromptu in B♭.
Rubinstein. Melody in F.
Chopin. Several of the Mazurkas.

A few remarks on the transcribing of pianoforte music for the orchestra will not be out of place at this point. Most young composers, from long acquaintance with the instrument, have acquired the habit of considering pianoforte music as the standard, and when they first attempt to write for the orchestra in nine cases out of ten they write first for the piano and then translate, as it were, their music into the orchestral idiom. This is a very natural procedure, and a by no means harmful one, provided a literal translation is not attempted, but the peculiarities of the orchestra kept in mind from the beginning. For instance, the number and position of the notes in a chord are limited, on the piano, by the fingers of the performer. Not so in the orchestra, where the performers are numerous. Thus the final chords of a piano piece may be illustrated as in Ex. 50. The top and bottom consist of a full chord, and the ear has accustomed itself to imagine the middle part to be filled in. But if we try this on the orchestra the gap in the middle would be painfully obvious; moreover, the thick harmony low down would be quite indistinguishable. It may be laid down as a rough rule that in a chord the parts should be tolerably evenly distributed; a larger gap is advisable low down (between the bass and the middle) than higher up. The natural series of harmonics given in Ex. 29 [page 5388] affords a good example of this treatment. So that our two chords should be scored as shown in Ex. 51.

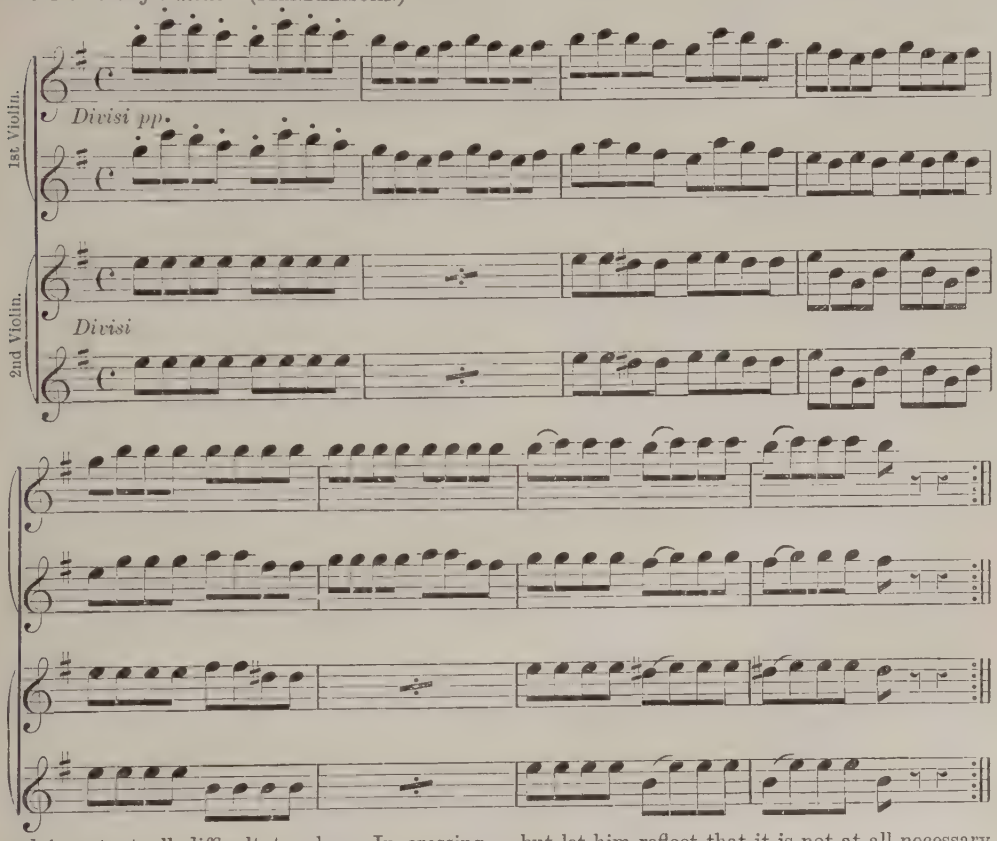
Acciaccaturas and Arpeggios. A device frequently met with in piano music to give the effect of widespread harmony is to write the bass note as an acciaccatura [52]. These notes are, of course, intended to be sustained by means of the pedal, and so the passage just given would be scored as shown in Ex. 53.

Another prominent feature of the piano is the ease with which extended arpeggios are played. There is no analogy to this in the orchestra, except on the harp. But the tone of this is so weak in comparison with the other instruments that it is hardly advisable to transcribe a pianoforte accompaniment as it stands for the harp. Some other means must therefore be sought for when translating this familiar feature.

Let us take a rather extreme instance. Chopin, one of the most pianistic of all composers, will furnish us with plenty. We select at random the Study in F major in the second book of Op. 10 [54]. The inexperienced student might think it possible to score this as it stands [55], but he

may be assured that the effect would be anything but pleasing; a passage so pianistic requires entirely remodelling to fit it for stringed instruments. In passing, however, attention should be drawn to the fact that when it is necessary to distribute a passage among different instruments, in order to avoid a "break" at the joins it is advisable to make the parts overlap—that is, to let the new part be taken up before the previous one ends [59]. However, even if this were done in the present instance the passage would still be uncomfortable, and to obtain the best result we must rearrange it, taking advantage of our knowledge of the violin family to make it lie well for the instruments. The translation given bears a considerable resemblance to the original,

Ex. 46. *Allegro molto* (MENDELSSOHN)



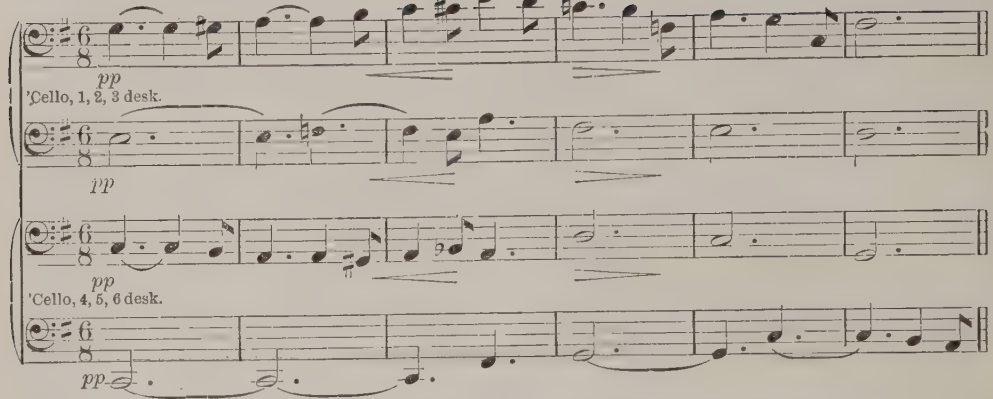
and is not at all difficult to play. In crossing the strings every use is made of the open notes [56]. But this is not the only possible version. Here is another even easier, though less closely resembling the original [57]. A few typical passages may here be given with a suggestion for their treatment, the device of double-bowed notes proving exceedingly useful [58, 60, and 61].

The Full Orchestra. The term "full orchestra" is used to denote the collection of instruments generally found at the principal London concerts, and for which modern composers are accustomed to write. It consists essentially of a fairly large and tolerably well balanced body of strings; wood-wind represented by two flutes, two oboes, two clarionets, two bassoons, with the addition, ad libitum, of a piccolo, cor anglais, bass clarionet, and double bassoon, and, on occasion, even further reinforcements; four horns (occasionally six or eight; these instruments are always employed in pairs), two or three trumpets, two tenor and one bass trombone, one tuba (these last forming a quartet of brass), two or three timpani, and other percussion instruments at the pleasure of the composer. A harp is a not infrequent addition.

The beginner will feel at a loss to know how to dispose of this great mass of instruments, but let him reflect that it is not at all necessary for all of them to play at once. In his first attempts at scoring he will do better to err on the side of thinness than the reverse, to which end he should start by writing for small orchestra, or, better still, for theatre band. Let him consider the wood-wind as the solo stops, as it were, of an organ, impressing his mind early with the precise tone-colour of each instrument.

It will be as well if, at this point, we consider the wood-wind apart from the rest of the orchestra, and afterwards endeavour to combine them with the strings. And, first, as to the tone-colour of each separate constituent. Can anyone who

Ex. 47 (WAGNER—"Siegfried")



has heard Dvorâk's New World Symphony forget the luscious effect of the flute low down in the phrase? [62] A typical instance of the higher register of this instrument may be found at the beginning of the second act of "Carmen," where two flutes play [63]. Owing to the flute's excessive delicacy the greatest care is necessary in accompanying a solo; strings should be almost invariably employed for the purpose. It may be stated, as a rule, that when a wind instrument has a melody, another instrument of the same kind should not be in use. This does not apply to the example above, where the two flutes in thirds form the essential feature of the melody.

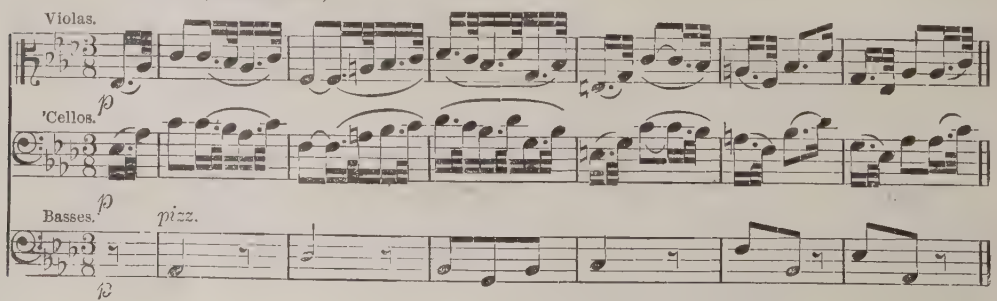
The oboe in solo work is best kept in the middle of its compass; the lowest notes are a trifle coarse, and the highest inclined to be squeaky. Its tone is so distinct from any other instrument that it will probably be the first the student will learn to recognise. It is well adapted to pathetic phrases and less suited to lively music, although, from its association, it is frequently used for a pastoral effect. One quotation will suffice, which, although rather high, is effective [64].

The clarionet is, perhaps, the most useful of all the wood-wind, partly on account of its extensive compass. Its tone-colour in the higher register differs considerably from that of its lowest octave, consequently it is possible to make an exception to the rule given above and allow a melody on one clarionet to be accompanied on another. The clarionet seems to have been Weber's favourite instrument, and a glance at almost any of his scores will reveal many beautiful and characteristic instances of its use. For solo use in the orchestra the bassoon has commanded less attention than it deserves; it has great expression of pathos on its higher notes, though florid passages low down invariably sound grotesque and comic. Beethoven, who treated all instruments with loving partiality, has left us some charming specimens of bassoon writing. Note the contrast between the mournful solo in the Rondo of the Violin Concerto [65] and a passage from the Fourth Symphony [66].

Besides these "primary colours" there are numberless others to be obtained by a judicious combination of wood-wind. A few of the simplest may be briefly mentioned. Flute and clarionet in octaves, usually with the former above the latter; a very sweet tone results from this combination if the music lies in a suitable register. By substituting an oboe for the clarionet the tone loses something of its pureness, but is rather more penetrating. Clarionet and bassoon in octaves is also effective if the melody does not lie too high. When more than three instruments are combined on one part the tone-colour loses distinction but gains in intensity, and additional instruments make but little difference except in tone-quality.

Although not strictly of the wood-wind class, the horn bears a decided resemblance to those, inasmuch as it combines beautifully with them and, furthermore, has valuable properties as a solo instrument. Its soft, dreamy tone in *piano* is unapproachable. In addition to this its tone in a *forte* is quite "brassy"; a passage for horns such as that shown in Ex. 67 has

Ex. 48. *Andante* (BEETHOVEN)



almost the effect of trombones. Since there are four of them in the orchestra, four-part harmony on horns is possible and exceedingly effective. Considerable use is made of them, moreover (especially by German and modern British writers), for filling in and sustaining the middle parts of the harmony, which gives an effect of fulness to the music; but this should not be indulged in to excess, as it results in monotony of colour.

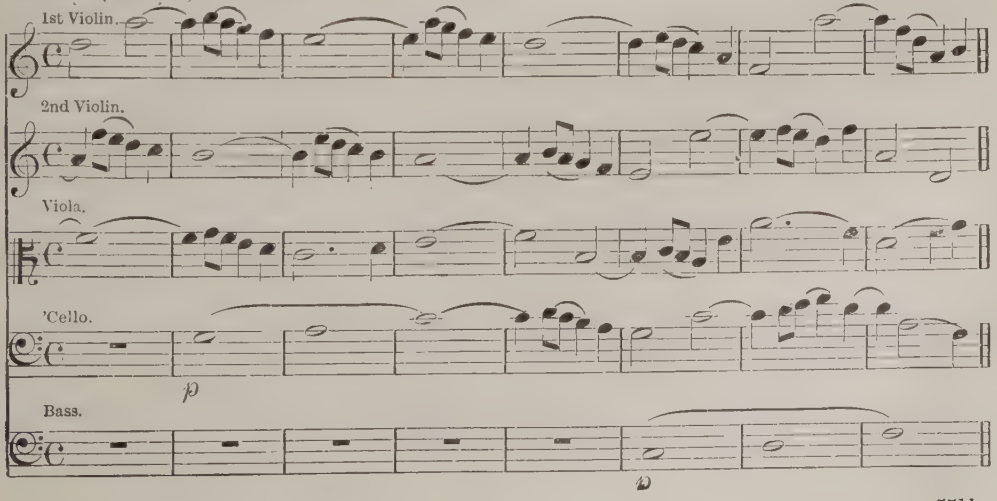
Now let us combine our forces, and add thereto a couple of trumpets, three trombones, and a pair of kettle-drums (timpani). This brings before us another question, balance of tone—that is, the different degrees of sound intensity possessed by each instrument. Until we know something of this it will be impossible to say, in any given passage, what will predominate. Normally, the highest part will stand out more than a middle one or the bass. But the matter is more complex than this. Score a few bars suitably for full orchestra, mark each part off, and what is the result? You will hear the trumpets, trombones, and drums; if the violins are written high up you may hear them to some extent. The wood-wind are inaudible.

Having learned from this which instruments can play the loudest, let us inquire which are best able to play *pp*. The honours are fairly divided here, but again the timpani may be considered to hold first place with an almost inaudible roll, followed closely by the strings, horns, and the low notes of the clarionet and flute. With these two exceptions the wood-wind are least able to play *pp*; that is, they have the smallest range of tone of any save the harp. This latter instrument is the first to be swamped by horns and wood-wind, and must be written high up if it is to be heard at all. In a *forte* without brass the strings have it all their own way, unless the wind are massed together high up, and even then the balance will not be good. In a passage from Beethoven's Fifth Symphony [68] it is probable that the imitation on the wood-wind has never been heard; if it has the conductor was responsible, not Beethoven. The weakness of the wood-wind when played against the strings *forte* has been insisted on at some length, as it is a fact invariably overlooked by the beginner, and his disappointment at finding a choice counter-subject rendered inaudible from this cause is generally the best reminder of the futility of his scoring. He is then apt to acquire an exaggerated idea of the weakness of the wind, and if he scores a pianissimo melody for, say, a solo 'cello with a light wood-wind accompaniment he will be horrified at the loudness and coarseness of the latter. This merely bears out what was said of the smallness of the wood-wind's range of tone. When anything like delicacy is wanted for an accompaniment the strings are unapproachable.

We are now in a position to score some simple pieces for full orchestra. The Menuetto from Grieg's Piano Sonata in E minor will be easy and effective for a first attempt. The opening might be given to the strings—it must be remembered that it is not necessary to lay out the harmony in "handfuls" when dealing with the orchestra; at the *fortissimo* the tone should be reinforced by the addition of the wind and brass, keeping the wood-wind high up and the brass nicely laid out over the harmony, the violins, perhaps, in octaves on the melody. At the double-bar the melody in thirds would fit two clarionets, accompanied by strings. The accents on the second beat might be reinforced with other instruments. The trio will afford a good opportunity for the wind and strings to be used antiphonally. Score the first eight bars for wood-wind alone; the flute had better have the top part, and the bassoons may be omitted or not, at pleasure. The succeeding eight bars should be strings alone. At the return of the minuet it would be well to vary the treatment somewhat, for the sake of variety.

Other pieces suitable for full orchestra will readily occur to the student. Beethoven's Funeral March from the Sonata Op. 26 offers good scope, Schumann's Carnival (a selection),

Ex. 49. (MOZART)



many of Schubert's marches, and Dvorâk's "Bohmer Wald" piano duets, although more difficult, would be very effective.

Before we can make any progress in modern orchestration it is, above all things, essential to the student to hear his work performed, however badly; and at that performance let him listen with all his intelligence alert, analysing every sound and comparing it with what his imagination had depicted. He will learn more from hearing and comprehending his errors than from pages of written instructions, provided he has acquired the groundwork, the technique, as it were, of orchestration. Much can be done from the study of scores, but only those he has heard and well remembers the effect of in performance. It will take years of experience before he can realise the sound of a score he has never heard.

Ex. 50.

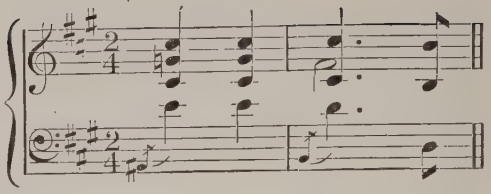
Ex. 51.

We can but briefly refer to the other varieties of orchestra previously enumerated.

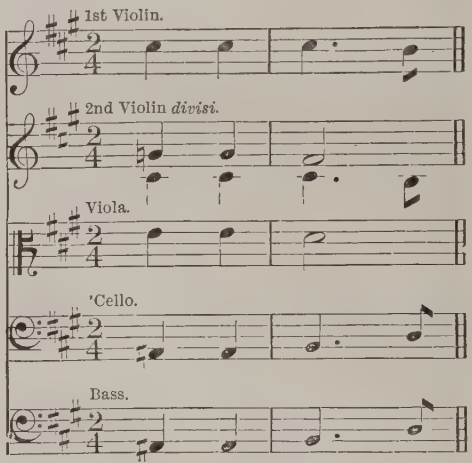
The Small Orchestra. The small orchestra, as written for by Beethoven and his contemporaries, is only the full orchestra with the trombones and the second pair of horns and all extra percussion omitted. The strings are also assumed to be reduced in number, and extra instruments, such as piccolo or cor anglais, are not admitted. Both in treatment and effect this orchestra may be considered to stand midway between the full orchestra and the theatre band, which latter will repay more detailed consideration than it generally receives.

The Theatre Band. The theatre band in its ideal form consists of these instruments: one flute, one oboe, two clarionets, one bassoon, two horns, two cornets, one trombone, one pair of timpani and various percussion, and a small selection of strings. With a band of these proportions the most charming effects can be produced, but alas! it is frequently found to be in a sadly mutilated condition. The horns may be missing, or the bassoon, then the second clarionet is dispensed with, and finally, from motives of economy, it is reduced to the septet band—string quintet, flute and cornet! Nevertheless, there are quite good theatre bands to be found in London and elsewhere, and we may devote a little space to their consideration, because it is most probable that the student's early

Ex. 52. (SCHUMANN)



Ex. 53.



attempts will gain a performance by this combination.

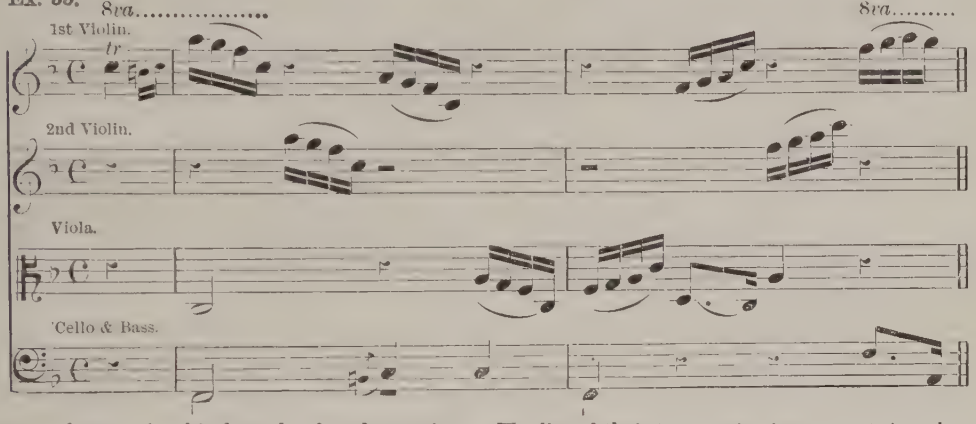
The methods employed with the full orchestra will want some revising for this differently balanced force. Take the brass for instance; the one trombone (a tenor) is apt to appear useless to the beginner, but by writing the cornets low down, three-part brass harmony is possible, and the horns may assist. The first cornet is perfectly well able (and willing) to play the melody, but is easily made to sound vulgar in this capacity, and for artistic scoring these useful instruments should be considered a compromise between trumpets and trombones: moreover, in the absence of horns they will make an efficient substitute.

The principal use of the wood-wind will be for solo work, but owing to the paucity of strings they seem to possess more sonority than usual. The clarionets and bassoon may be used for sustaining harmony in the middle.

But it is upon the strings that the chief burden of the orchestra will rest. Even more than before is this the case, and it is but seldom that we can afford to leave them out entirely. Owing to their small number it is not often advisable to divide them, although this has been done at times with wonderful effect. It should be remembered that as the orchestra is somewhat sunken the scoring may be made rather thicker and noisier than would be good for the concert platform. But much will depend on the purport of the music; if it is incidental music, to be spoken through, it cannot be made too light, and the wind had better be eschewed almost entirely. There is

Ex. 54. (Chopin)

Ex. 55.



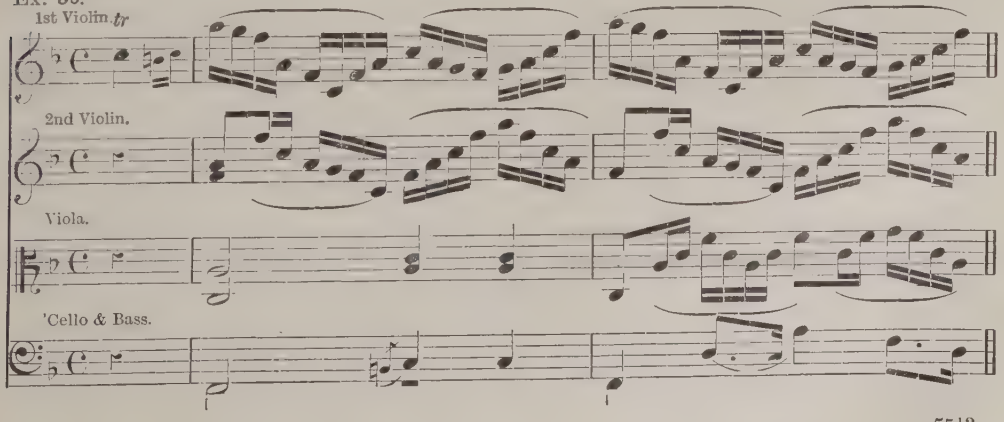
plenty of scope in this branch of orchestration for improvement; the ordinary composer of light music seldom troubles to think out new effects of scoring.

The Wind Band. The wind band, as found in this country, is not a very artistic combination. It consists, approximately, of flute, oboe, two clarionets, two horns (sometimes omitted) two cornets, trombone (sometimes two), euphonium and side-drum, thus bearing considerable resemblance to the theatre band minus the strings. It is unnecessary to say more of this than has already been written; only the simplest kind of music is suitable for such treatment.

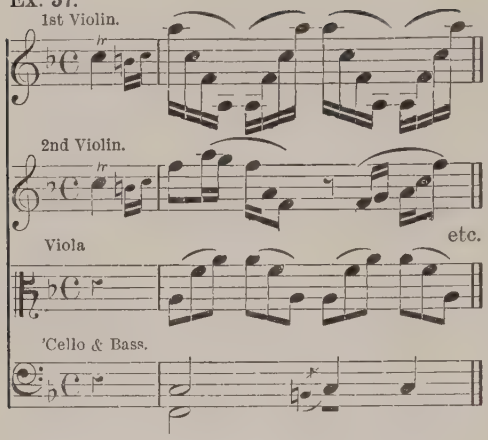
The Brass Band. The brass band, such as is heard chiefly in the North of England, approximates somewhat to the military band. The list of their transposing instruments is rather terrifying. The latter is constituted something as follows: Piccolo in E♭, flutes in D♭, oboe, clarionets in E♭, first clarionets in B♭, second clarionets in B♭, third clarionets in B♭, alto clarionet in E♭, four horns in E♭, two cornets in B♭, two bassoons, two trumpets in E♭, two baritones in B♭, two euphoniums in B♭, three trombones, two bombardons in E♭, contrabass tuba in B♭.

In the brass band the wood-winds are omitted; sometimes the clarionets are substituted by saxophones, which take the place of violins; failing these the cornets take their place. It is unlikely that the student will want to write for either of these combinations, moreover some acquaintance with the technique of the instruments is almost a necessity.

Ex. 56.



Ex. 57.



In conclusion a few practical hints may be of service to the inexperienced student. The order in which the instruments are arranged in the score has undergone some modification, but the most usual, and the one which cannot be bettered, is this. First, the wood-wind in order of pitch (reckoning the lowest note of each); the horns, followed by the rest of the brass; next the percussion (to save space they may, with the exception of the timpani, be written on a single line); the harp (if used). In a vocal work the voices may come next, and, lastly, the strings.

Ex. 58

Piccolo, flutes, oboes, cor anglais, clarionets, bass clarionets, bassoons, double bassoon, horns, trumpets (cornets), trombones, tubas, timpani, triangle, bass drum, etc., harp, voice, first violins, second violins, violas, 'cellos, basses.

The voices are sometimes put in the midst of the strings, just above the 'cellos, but it is better to keep the strings together.

It is customary to put reference marks at short intervals in the score to facilitate matters at rehearsal. Letters are frequently used, inserted usually at the beginning of a phrase or other likely starting-point. A still better device is to number every tenth bar consecutively. This affords additional protection against bars being left out by the copyist.

In copying out band-parts it is well to endeavour to bring a "turn over" at a point where the instrument has a few bars' rest, even if this necessitates wasting half a page of paper. If this is impossible it should be arranged that the string parts each turn over at a different point. For the same reason the two flutes are written in parallel staves on the same paper, and the other wind correspondingly, so that the second may turn over if the first is playing at the end of a page. After a good many bars' rest it is safest to write in a "cue" in red ink, previous to the instrument's re-entry. Attention to these details will assist in obtaining a smooth performance.

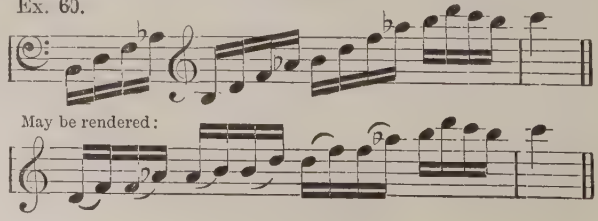
CONDUCTING

Anyone who has ever taken part in a pianoforte or vocal duet must have experienced some little difficulty in keeping strict time with his fellow performer. Failure in starting together, and the slight fluctuations of time that are necessary for a musical performance, are generally the blots on such duet playing. If he has played in a quartet the student will have observed this difficulty still more strongly; a nice *ensemble*, as musicians call it, is only to be obtained by constant practice, until not only the work under performance but each of the players' idiosyncrasies become familiar to all the performers. If, now, we imagine a performance by from 20 to 100 instrumentalists, the difficulties will be immeasurably increased. How are they to decide simultaneously the moment of starting? How agree upon the precise *tempo?* (The Italian word "tempo" is used throughout to denote the rate or speed of performance; time, the English equivalent, refers always to the time-signature—that is, the number and value of the notes in the bar.) How, in short, can they give a performance that shall be in any way unanimous without an infinitude of rehearsing? It will at once be obvious that there must be one master mind to direct the powers of the others, and that these must, for the time being, be subservient to the director. We may gather from this what are, in part, the functions of the conductor in the orchestra or choir.

Ex. 59.

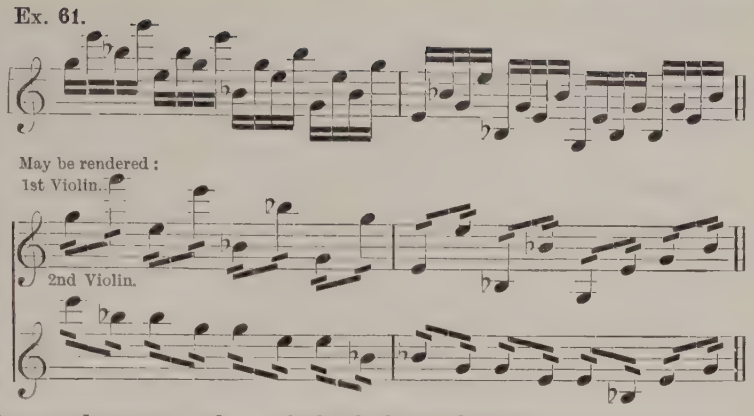
Until about eighty-five years ago the orchestra was conducted by the joint efforts of the principal first violin (who is still called the leader), and a pianist, whose duty it was to fill in any obvious gaps caused by the faulty playing of the

Ex. 60.



orchestra. This unsatisfactory state of things continued (in England) until 1820, when Spohr, conducting the Philharmonic concert in London, directed the performance with a *baton*, a light staff of wood with which he beat time and gave the necessary indications to the band. The immense superiority of this method was so apparent that it soon became universal and has remained so ever since.

Ex. 61.



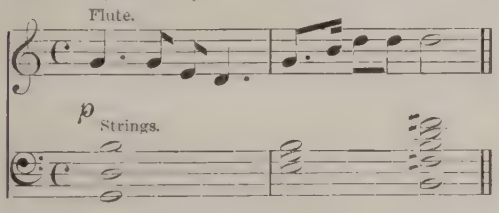
The requirements of a conductor may be grouped under two heads: (1) The technical knowledge of the code of signals and gestures used to indicate the different times, rhythms and nuances (light and shade); (2) the æsthetic knowledge of the requirements of the music. It is only the technical side of conducting that can be taught here on paper; the æsthetics of music can only be learned by an exhaustive study of the scores and by listening to performances under the best conductors.

It is necessary that every movement of the conductor shall be deliberate and decided. Any hesitation that he may show will be reflected by the players under him, his indecision will be shown by them, hence he must be very certain of what he has to do. The baton must be held lightly, and the arm and wrist should be free. The baton should be kept sufficiently high to permit of its being seen by everyone, yet no higher than is necessary or the arm will quickly become tired.

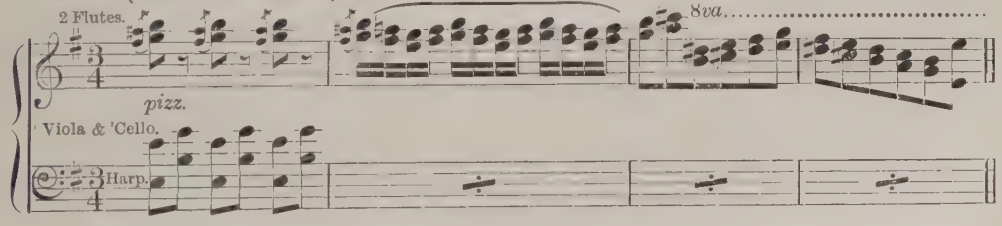
The student will probably know enough of musical theory to remember that the first beat of every bar is the most important; it has normally the strongest accent, and is invariably indicated by the conductor by means of a down beat [1]. The down beat should never be used except on the first of the bar; it follows that the preceding beat—that is, the last of the bar—will be upwards. The remaining beats will be filled in variously, according to circumstances. The principal varieties may be thus tabulated, the direction of the beat being shown (approximately) by means of diagrams. Two in a bar, first down, second up [2]. In a very slow movement in duple time it may be necessary to beat four in the bar. Three beats in the bar, first down, second either right or left, third up [3].

If any of the players are seated behind the conductor the second beat should be to the right, so as to be more visible; if all are in front of him it is quite immaterial which

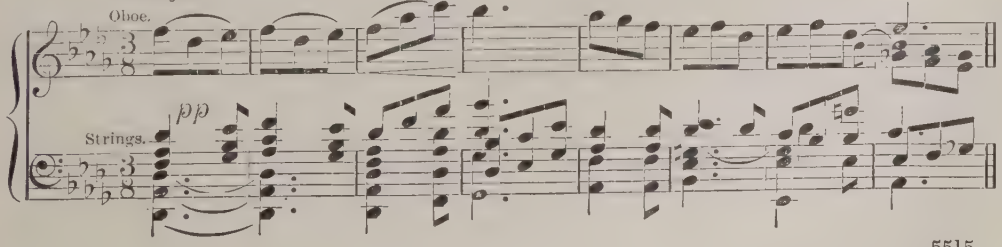
Ex. 62. (Dvořák)



Ex. 63. (Bizet—"Carmen")

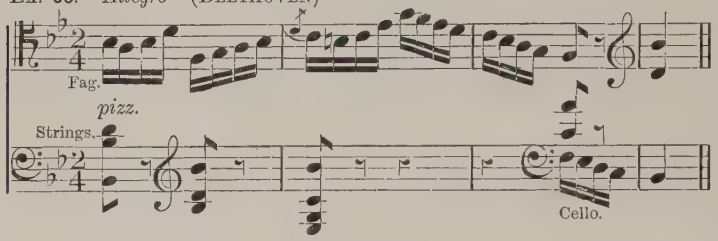


Ex. 64. *Adagio*



Ex. 65. (Beethoven)

Ex. 66. *Allegro* (Beethoven)



direction is taken. In a very fast 3–4 movement, such as the scherzo of Beethoven's Pastoral Symphony, there is no time for three separate beats, and "one in a bar" should be indicated by means of a decided down beat on the first and a quick up-beat at the end of the bar.

Four beats in the bar, first down, second left (generally), third right, fourth up [**4**]. Some conductors reverse the directions of the second and third beats.

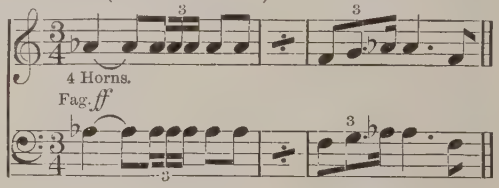
Six beats in the bar. This will be indicated in two different ways—according to whether the time be compound duple (6–8 or 6–4) or a slow triple (3–2 or 3–4). The former case will require two strong beats on the first and fourth of the bar, each followed by two lesser beats [**5**]. The latter will be similar to three beats in a bar with each beat duplicated [**6**]. Six and more beats are only required in very slow tempo, as they will all be found to be compound varieties of duple, triple, or quadruple times.

Eight and twelve beats are both compound varieties of four in a bar, each beat being duplicated for eight, or triplicated for twelve [**7**], while nine [**8**] is three with each beat triplicated.

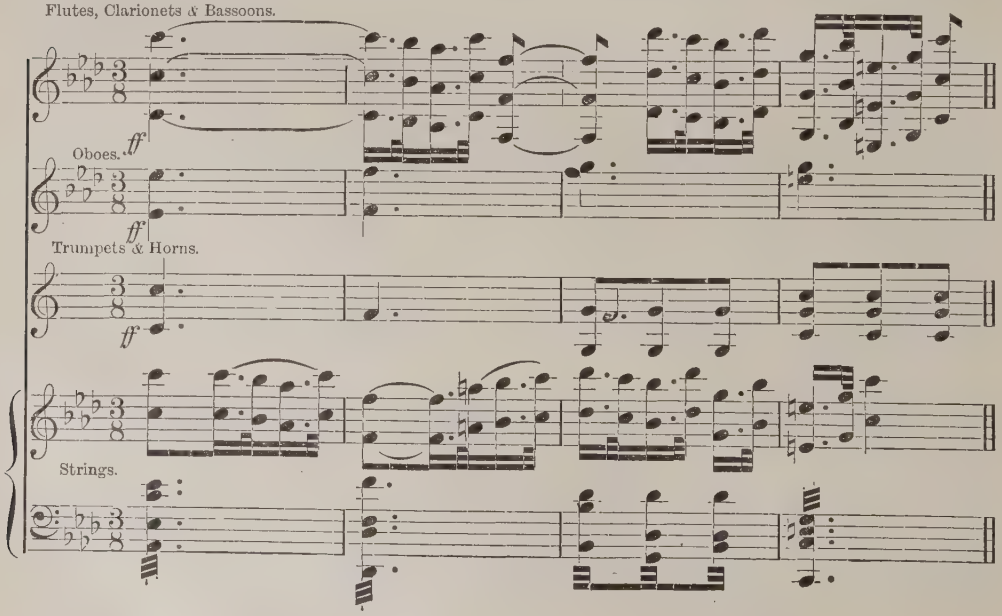
The irregular rhythms of five and seven beats in a bar. These will generally be found to consist of a bar compounded of alternate two and three, or four and three, and may be beaten as such if the first of the bar be made clear. Or five may be beaten as diagram **9** shows.

The movements necessary in beating time should be made freely and decisively, without being jerky. They should be so familiar as to be performed semi-automatically, so that the conductor's whole attention may be given to the requirements of the music. Nothing could be more disastrous than to find the conductor

Ex. 67. (Tschaikowsky)



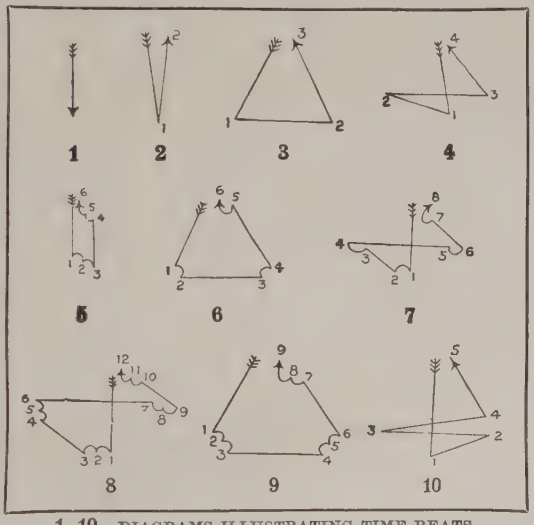
Ex. 68. (Beethoven)



unprepared for a sudden change of time. This, of course, requires that he be well acquainted with the work under performance, and however great his talents, he should not permit himself to follow the example of a certain well-known musician who makes his acquaintance of a new work while he is conducting the first rehearsal of it.

At the start of a piece or movement the baton should be held poised in the air for a few seconds until the conductor is sure of the attention of the whole orchestra, and the first down beat should be prefaced by a short up-stroke, which will have the effect of giving a more decided and definite start. If the music begins on some beat other than the first it is not advisable to beat the whole bar (unless it be indicated in the score by rests), as this may cause confusion to such of the orchestra as are counting several bars' rest; but the starting beat should be preceded by a slight preparatory movement.

Exaggerated Gestures. Apart from the actual beating of time, numerous other indications as to the manner of performance can be given with the baton or by means of gesture on the part of the conductor; but a word of warning must be given against the habit of exaggeration in gesture. Nothing looks worse than to see a conductor enacting movements of fury in order to obtain a *con fuoco* from his band. Any special climactic effects should be spoken of at rehearsal, and a slightly broader gesture may be used in performance by way of a reminder. A pause on a note is held by keeping the baton stationary on whatever beat it occurs—usually the first or strong accent. It is released by a short upward flick of the end of the baton. There should always be a brief interval of silence after a pause on a note before continuing. A pause on a rest is, perhaps, better indicated with the baton held poised in the air as at starting.



1–10. DIAGRAMS ILLUSTRATING TIME BEATS

At the conclusion of a piece the sound should be sharply cut off by a quick upward flick of the baton. It may be taken as a general rule that light and *piano* characteristics should be accompanied by small and delicate movements, chiefly from the wrist, the increasing size of the beats to correspond with the increase of tone required and the gesture becoming broader as the music does likewise. It is assumed that the baton is held in the right hand, but it is often advisable to use the left hand with it for supplementary gestures, indicating breadth and climax—indeed, many conductors use the left hand as much as the right, and would probably be unable to keep it still without an effort. The left hand can also be used for a gesture signifying extreme softness; this is especially useful for a sudden *piano*.

The Position of the Players. When any instrument has had a number of bars' rest it is well for the conductor to make his re-entry certain by giving him a signal. A glance in the direction of the player or players just preparatory to their re-entry will afford the necessary indication for their guidance. It follows that the conductor must know the position of each instrument in the orchestra. This varies a little according to circumstances. In a theatre, band space is usually restricted, and the conductor may congratulate himself if his trombone and timpani are not outside in a passage where he cannot see them! But in the concert orchestra the arrangement is usually thus, from the conductor's point of view: The first violins are on the left, the seconds on the right, the violas in a line in front, the 'cellos sometimes behind the violas, but frequently divided right and left as are the double-basses. Occasionally they play at the same desk as the latter—that is, one 'cello and bass to each desk—this is behind the violins. The woodwind (flutes, oboes, clarionets, bassoons) sit in a line behind the violas; if the space is small they may be in two rows; behind them are the horns and trumpets, the trombones and percussion occupying the backmost seats. If there is a harp it is placed as near the conductor as possible. This is necessary partly on account of the weak tone of the instrument, but also because the harpist requires more personal attention than the rest of the orchestra.

This arrangement must not be taken as invariable, but merely the usual disposition of the band at London orchestral concerts.

The Conductor's First Performance. Now, our first experience of conducting may occur in several ways. The composer may be asked to conduct a performance of his own work by a more or less well-known orchestra (not otherwise will the student be permitted to experiment on a good band), or he may get together an amateur orchestral society and appoint himself conductor, or he may possibly obtain the conductorship of a theatre band. We will consider each of these possibilities in turn.

If it is his own composition that he is conducting, the student starts with one great advantage; he knows the work in question

thoroughly at the start, and can give all his attention to what he is doing. Very probably there will be only one rehearsal, so he must make the utmost of his time. His first undertaking will be to see that the band parts are all correct, for, however carefully he has looked through them, there will always be mistakes somewhere. He must listen very carefully in order to detect which instrument is in error, and the moment he stops to effect an alteration he will find half the band clamouring to have mistakes, hitherto unsuspected, rectified.

These preliminaries require a clear head and a well-trained ear, besides unlimited patience, if they are to be gone through successfully. If the orchestra is composed of good and experienced players, it is not advisable to stop them too often, except to set right anything important, as they can be trusted to notice and correct little errors for themselves, and it is impossible to get an idea of the music as a whole if the band is stopped every few bars. Any fluctuations of time (*ritardando* and *accelerando*) will be indicated in the parts ; this will warn the band to follow the beat carefully ; but such changes of tempo must be very clearly shown, and must not be made too abruptly.

The Limitations of Amateurs. It requires considerable courage for the beginner to conduct another man's well-appointed orchestra for the first time ; but, given a band of amateurs, the youthful conductor, if he has had any musical training, may feel far more confident and despotic. He should be warned, however, not to be too ambitious, but to suit his programme to the capacity of his orchestra ; for the majority of amateur instrumentalists are, to say the least of it, indifferent readers. So it will often be advisable to take to pieces any difficult passage that may present itself, rehearsing, say, the wood-winds alone, to obtain the necessary *piano*, the violins by themselves (more especially the seconds) until they can play that semiquaver passage nicely together ; the brass, if there is any, that we may hear who it is playing a wrong note, and so forth. Before conducting well-known works the student must ascertain the correct tempo throughout, and should not deviate from the traditional reading without sufficient reason until some years of experience lie behind him.

Conducting Theatre Bands. We now turn to the theatre band. This is a capital medium on which to expend one's embryo efforts of conducting, besides being a fruitful source of experience. Its composition varies from the string quartet, cornet, and piano of the provincial "smalls" to the well-developed orchestra now to be found at a few of the best London theatres. It differs in many respects from either of the varieties of orchestra that we have so far considered. It is smaller in size ; it occupies usually a more enclosed space ; is frequently out of sight of the listener, and it is not listened to with very much attention. It is on account of these seeming drawbacks that the band is more easily controlled by its conductor. He can do things which would be impossible in a concert-room ; on an emergency he may even speak with the players. The necessity for this facility of control is seen when the band is playing music incidental to the stage performance. It may have to follow the action of the play, which only the conductor can see ; he may have to make sudden alterations of tempo, pauses where none exist, repeat sections *ad libitum*, or leave out repeats.

Impromptu Work. At times the conductor may have to give out band-parts and perform at sight extra numbers to fill in a delay between the acts ; in the middle of this the curtain will perhaps rise, and the conductor must stop abruptly at the nearest cadence. This sudden stoppage can be indicated to the band by a look and an appropriate gesture ; a *ritardando* will even suffice for the experienced bandsman. If there is no possible stopping-place in the music a *diminuendo* until the sound is practically inaudible is the only resource. In dance music, where every section is marked with repeats, the conductor is accustomed to tap the desk twice in quick succession to indicate "Go on, omit the repeat," where such omission is desired. It will be found that much light music of which band-parts are obtainable is unprovided with a full score, and the conductor has frequently to be satisfied with a first violin part ; but music of this character is so simple that this is not a great drawback. In very small orchestras the conductor may be expected to play first violin himself, leaving off to beat time with his bow when necessary.

CHOIR TRAINING

In writing for the purpose of assisting the inexperienced student over his earliest attempts at choir training, it is necessary to consider in what circumstances he is most likely to need this assistance. It is not in connection with a well-appointed choral society that these initial efforts will take place. We are writing, be it remembered, of choir *training*, not choir *conducting*, and in order to obtain a post as choirmaster to an even moderately good choir a certain amount of previous experience is almost a necessity. It is probable that the student's first efforts will be expended on a small and very indifferent church choir, the post of choirmaster not infrequently being combined with that of organist.

That such a choir will most likely be small, badly balanced, and badly trained (or else not trained at all) is in some respects an advantage, as the opportunity is offered of learning the work from the very beginning ; and if the student is anything of a musician he will instinctively realise how much there is for him to do, and in his energetic attempts to reduce chaos to some order he will lose that feeling of "newness" to the task, and experience will rapidly come to him.

The Arrangement of the Voices. A choir, if it is to be worthy of the name, should be divided into four parts or voices—trebles, altos, tenors, and basses, and this arrangement should be adhered to wherever possible, as by far the greatest amount of choral music is written for this combination of voices. The first difficulty

to be encountered is to select the members for these four parts so that a tolerable balance is obtained. If the trebles are sung by boys' voices, as is very usual, they will require to be more numerous than the other parts; indeed, they may be equal in number to the other three combined without causing any serious disproportion. The altos generally give the choirmaster the most trouble. If there are ladies in the choir, well and good, but if not, the male voice is rare and difficult to obtain, and boys' voices will have to be employed for these. A fair proportion for a choir of 20 would be: 10 trebles, 3 altos, 3 tenors, 4 basses. If the trebles are sung by women the proportion to the other parts may be rather less. Thus our choir of 20 might contain 8 trebles, 4 altos, 4 tenors, 4 basses. Perhaps a further improvement would be an additional bass or two.

It has been said that the functions of organist and choirmaster are generally united in one individual, hence it will be obvious that at the preliminary practices any organ accompaniments are out of the question; the choirmaster will want to give all his attention to conducting the choir, any accompaniments that may be necessary to preserve the intonation (and the less the better) can be played on a piano.

Preliminary Instruction. It will perhaps be as well if we assume that the choir we are considering is entirely new-formed, and has had no previous training. Our first care in this case should be to take the younger members by themselves and impart some instructions in the rudiments of music, paying more especial attention to such matters as concern the relative values of notes and rests, time signatures, and the like. A blackboard ruled with music lines should be provided, and exercises in time written thereon should be sung at sight and repeated a few times until absolute accuracy of notes and rests has been acquired. The above is a specimen of exercises for beginners, the conductor indicating each beat with a baton, first quite slowly and afterwards at a quicker speed.

Such exercises should be invented by the choirmaster on each occasion, and not used over again, as they are intended to be preliminary to reading at sight. They should be sung to the sounds "ah" or "la," the broad vowel sound being generally preferable to a closer one.

Next, simple intervals may be introduced into the exercises; and now it must be decided whether *Tonic Sol-Fa* or *Staff* notation is to be taught. It is not proposed to enter here on a discussion of the merits of these rival systems. The choirmaster will probably have a predilection for one or other. The Tonic Sol-Fa is undoubtedly the simpler, and is said to give the best results with pupils of limited intelligence. Staff notation, on the other hand, renders a vastly larger repertoire of music available to its disciples.

Until the choir has attained considerable facility in singing simple diatonic intervals, no attempt should be made to introduce words. The syllables Do, Re, Mi, Fa, Sol, La, Ti (or the Tonic Sol-Fa equivalents) can be used for the degrees of the scale.

Exercises. The next stage should be the introduction of simple two-part exercises, which the choirmaster may either invent for himself or else obtain from one of the many collections published for the purpose. Both parts should be practised separately, especially the seconds, before they are sung in combination. This remark applies even more forcibly with regard to the full practice, which should take place at least once a week; each single part must receive separate rehearsal before the *ensemble* is attempted.

We have now advanced to the stage when easy four-part anthems may be rehearsed. And here it may be as well to repeat the advice just given—until the music is fairly well known, no words should be sung, only the syllables representing the notes of the scale. The reason for this is obvious. We do not wish the attention of the singers to be divided between two entirely

different and almost equally difficult tasks, for the correct pronunciation of words in singing is frequently a source of much trouble, even to such choristers as have had a good education. The vowel-sounds in the North of England are often compounded in a fearful and wonderful manner; for that matter, London itself has some strange perversions of English pronunciation, such as the conversion of the long ā into ie, and so forth. It follows that exercises in the simple vowel-sounds will be required. A series of such sounds may be recited or sung to a monotone. For instance:

ā	â	ă	ē	ĕ	ī	ĭ	ō
May	ma	mat	neat	net	bite	bit	note

ŏ	ōū	ŏŭ	ŭ	ū	āū	ow	oy
not	boot	foot	but	tune	caught	now	boy

These comprise all the vowel sounds in the English language. Among the consonants that will require attention the letter R may be picked out, especially as a final, and before a vowel; indeed, almost all final consonants will show a tendency to be eluded, and the latter H will probably want some attention. Some attention, too, must be given to breathing. If not already marked, the teacher should indicate the places in the music where breath is to be taken, and see that it is done quickly, and above all, silently.

Blending the Parts. As regards *ensemble*, or the nice balancing of the parts one against the other, the members of the choir should be taught from the very first the necessity of listening to the other parts, and so endeavouring to make their own efforts blend with the others. They must not consider their own part as the most important, unless it is solo work they are doing, but should try to sink their own individuality for the benefit of the choir as a whole.

Varieties of Sugar. Cultivation of the Cane. Separation of the Juice. Clarification. Concentration. Evaporation and Crystallisation. Curing.

CANE SUGAR & ITS MANUFACTURE

ORIGINALLY regarded as a medicinal confection, sugar has become one of the most important foods of the human race. The world's production is estimated at from 15 to 20 million tons, and the consumption of sugar per head of the population in the United Kingdom is over 95 lb. per annum. Chemically, sugar is classed with the carbohydrates, and the various kinds of sugar may thus be divided :

1. Saccharose, or cane sugar ;
2. Lactose, or milk sugar ;
3. Glucose, or grape sugar ;
4. Levulose, or fruit sugar ;
5. Maltose, or malt sugar.

Saccharose. Saccharose, the most important sugar, is very widely distributed throughout the vegetable kingdom. The chief sources are the sugar cane, the sugar beet, palm, maple, sorghum, and maize, the first two yielding the bulk of the sugar supply. Sugar is a crystalline solid, freely soluble in water, a cold, saturated solution containing over 65 per cent. of sugar, while as much as 82 per cent. of sugar can be taken up in a boiling solution. If a strong solution of sugar be slowly evaporated, crystals are obtained, which, if allowed to deposit on string, form *sugar candy*. When sugar is heated it melts, and if then allowed to stand till cold yields what is known as *barley sugar*. By combining butter and flavouring matter with melted sugar the familiar *butterscotch* is produced. If strongly heated, sugar darkens and gives a coloured product known as *burnt sugar*, or *caramel*. Sugar is the source of alcohol in wines and beer, although cane sugar is not itself directly fermentable, but has to go through an intermediate stage before being acted upon by yeast. The question is often asked : What is the difference between beet and cane sugar ? The answer is that sugars from any source are indistinguishable if equally purified.

There is a slight difference in the amount of ash yielded by the two, and also a chemical difference in the constituents of the ash.

Lactose. This is also known as milk sugar, as it is the only carbohydrate of importance in milk. Milk sugar is not so sweet as cane sugar, and is only soluble to the extent of one part in six of cold water. When fermented with certain yeasts, milk sugar yields the drink called *koumiss*. Large quantities of lactose are used as a food for infants and invalids, and a smaller proportion is employed in the preparation of medicines.

Glucose. Other names for this are *dextrose* or starch sugar. It exists in grapes and honey, but is made on a manufacturing scale by acting on starch with a dilute acid. Liquid glucose, or *starch syrup*, as well as solid glucose, is produced, and the residue from the manufacture, known as *climax sugar*, is used by brewers for colouring porter. Glucose dissolves in water, but it is only about half as sweet as cane sugar. It is readily fermentable, and yields 48·67 per cent. of alcohol. The chief uses of glucose are in the brewing of beer, the manufacture of confectionery and jams, and in calico-printing.

Levulose. This exists in honey and ripe fruits, but is made commercially by the action of weak acids on sugar solution, the product being known as *invert sugar*. Pure levulose can be obtained from inulin, the starch contained in the dahlia, inula, and chicory. It is sweeter than saccharose, and very soluble in water. Invert sugar is of considerable importance in brewing.

Maltose. Malt sugar is formed by the action of malt extract on starch, and yields, when fermented, 50 per cent. of its weight of alcohol. By boiling with dilute acids it is converted into glucose; it is always present in commercial glucose.

Cane Sugar. The sugar cane which yields this sugar is a huge grass with a knotty stem. It belongs to the natural order *Graminaceæ*, and is known botanically as *Saccharum officinarum*.

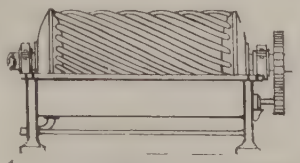
By cultivation many varieties have been produced, the principal ones being the Mauritius, the Laina, the Otaheite, the Bourbon, the Ribbon, the Java, the China, the Singapore, the Indian, and Cristalline. Some of these are probably distinct species, such as the China sugar cane ; the others differ from each other in the colour and hairiness of the stem. Some varieties are preferred in certain situations, the Cristalline cane, for example, having a reputation as a disease-resister in the French West Indies. The Bourbon cane was originally introduced into the West Indies from the Isle of Bourbon. The varieties most in request are long-jointed canes, the leaves from which are readily detached from the stem as they die. As a rule, however, it may be taken for granted that each country has produced a special variety of cane suited to its climate and soil.

The sugar cane grows in a wide range of climatic conditions, but flourishes best in high latitudes, on account of the greater length of the days, and attains its greatest perfection within the tropics. Light is essential to the storage of sugar by plants, the erect habit of the sugar cane having an important influence in obtaining the maximum of sunlight.

What the Cane is Like. The sugar cane is perennial, and produces a stem 8 ft. to 12 ft. high and 1 in. to 2 in. thick, while there are from 40 to 80 joints. The leaves are produced at the joints, and are 4 ft to 5 ft. long and 2 in. wide. As the canes grow, the lower leaves dry up, fall off, and are removed, the process being known as *trashing*. The sugar cane needs a fertile soil, clay and sandy soils being unsuitable. In French Guiana the only remunerative cultivation of the sugar cane is on low lands that are periodically manured by flooding with water from which black mud is deposited. In Queensland, land of virgin soil is prepared by light ploughing to get rid of grass. The ground is then ploughed 9 in. to 10 in. deep, and worked with the harrow and roller to ensure sufficient soft mould for the plant.

Propagation. The sugar cane is propagated from cuttings or seed, but usually by the former method, seed being only used for obtaining new varieties. The cuttings may be either from the top

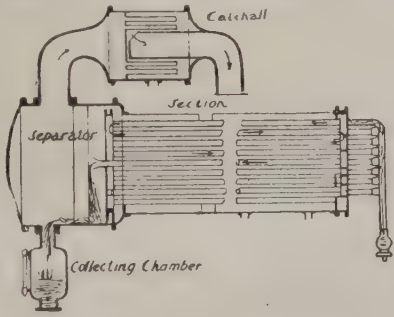
or from the body of the cane, and experimental work in the Mauritius seems to indicate that the tops are preferable. If *tops* be used, the leaves should be stripped from two or three buds, so that they can come into immediate contact with the soil. If *plant canes* be used, they should be cut into lengths of three buds each, care being taken not to injure the buds. The plants are then placed in drills at a distance of about 3 ft. from centre to centre. The canes are placed horizontally, and with the buds pointing one way; 1 in. to 1½ in. of mould above the cutting is quite sufficient, since it will grow more rapidly than if planted deeper. After a few days, according to the weather, rootlets will spring from the joint surrounding the bud, and in from ten to twenty-one days the buds will begin to appear above the ground.



1. THE WETZEL EVAPORATOR

Cultivation. All the cultivation afterwards required will be to keep the ground open and clear of weeds as long as the horse-hoe can be used, after which the ground can be left until crushing season. Cutting of the cane is effected in several ways—some are cut with a knife, the cane being trimmed and topped while in the hand, while others are cut with a sharp hoe, the trimming and topping being done by another group of labourers. When the cane is light upon the ground, or stands erect, the former mode seems preferable, but where the crop is very heavy the latter method is used. In either case care should be taken to cut the cane close to the ground, as the *ratoon* (the cane which springs up from the stump) will rise from the highest bud on the cane root left; and if this be not below the surface, support against the wind for the young cane will be lacking. The practice of different plantations varies in regard to replanting or growing from ratoons, for although cane will retain and yield crops for several years without replanting, ratoon crops are not so heavy as those of plant cane.

Manures. We now come to consider the various manures that are necessary. Phosphatic manures give considerable and very remunerative increase when used together with manures containing nitrogen and potash. Phosphate slag seems to be an excellent source of phosphorus for cane plantations, and ought to replace superphosphate. Nitrogen, in the form of sulphate of ammonia, nitrate of soda, and dried blood, shows a favourable influence on the yield. The best results obtained by the authorities of the Botanical Gardens of British Guiana were obtained with a mixture of one-third nitrate of soda and two-thirds sulphate of ammonia, although for large quantities sulphate of ammonia gives a better pecuniary result. The whole object of manuring is to supply to the plant those chemical constituents in which the soil is deficient.



2. THE YARYAN EVAPORATOR

Diseases of the Cane. The cane is subject to a variety of animal and vegetable pests. In the first category are included rats. These are kept down by poison or the use of the Liverpool virus. Among insects the moth-borer is prevalent, and is only got rid of by systematically collecting the moth and destroying the diseased canes by fire. Several other borers are known, some of the pests making special attacks on the roots of the cane. Spraying with paraffin emulsion is recommended for destroying some of the small insects. Vegetable or fungoid pests, such as red smut, top rot, sereh, ananas, and gumming disease, attack the leaf and stem. The remedies are to choose canes known to be disease-resistant, to correct errors of cultivation, and to destroy all affected canes by burning. Rotation of crops and green manuring are also a means of combating fungoid diseases.

Harvesting. The ripe canes are cut with hatchets, close to the ground. The top joint is discarded, and all the leaves are stripped off. Damaged canes are separated, and the cut canes tied in bundles for conveyance to the factory by wire tramways or other means. The weight of crop varies very much, from 70 to 80 tons having been taken from rich scrub-lands in North Queensland. A fair average is 25 to 40 tons per acre, and with modern appliances and methods a ton of sugar is sometimes made from little more than ten tons of cane. There is 16 to 18 per cent. of sugar present in the sugar cane, and about 70 per cent. of water. The sugar is distributed irregularly throughout the cane, the joints and the lower end being poorer in sugar than the higher parts.

Processes of Manufacture. The sugar cane is passed through a sugar mill, and the juice that is expressed is submitted to processes of purification. The juice is concentrated until the sugar is obtained in a crystalline form. The sugar is then prepared for the market, or "cured," and the molasses treated so as to recover from it any remaining sugar. These processes are conveniently considered in the following divisions:

1. Separation or extraction of the juice.
2. Clarification and defecation of the juice.
3. Concentrating and crystallising.
4. Curing or cleansing the sugar.

Separation of the Juice. The cut canes are passed through a mill, which squeezes out the juice. The oldest form of cane mill was provided with wooden or stone rollers, but, except in some parts of India, these have been replaced by iron mills. The three-roller mill is the most used. In this, one roller, the "head" roller, is placed above the other two, and moves in the opposite direction to them. The mill is so arranged that the cane can enter easily, the pressure being increased by the adjustment of the rollers. In Stewart's cane mill additional power is obtained by means of a massive crushing head forced down by hydraulic pressure. Merrilees, Watson & Co. dispense with the use of hydraulic appliances, and make a mill with yielding ends, by means of *toggle* levers acted on by springs.

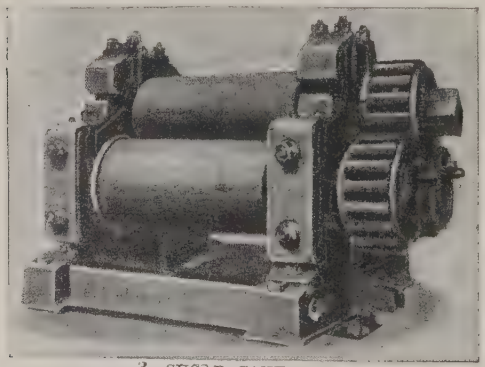
The mill automatically relieves the pressure on one or more rollers, and prevents jamming in case of irregular feeding. Simpler forms of mill have but two rollers [3], and others are used having rollers up to eight in number. The mills are often

fed mechanically. As the crushing mill does not press out the whole of the juice, double and triple crushing is employed, and sometimes the crushed cane is soaked with hot water in its passage from one mill to the other. It is not possible to extract the whole of the sugar, but the loss is reduced to about 1 per cent. Other methods embody the use of a diffusion process—a soaking in hot water in closed vessels—between the two crushings. The *bagasse* (crushed cane) from the first mill is passed into diffusers containing heated water, and after a time the bagasse is drained from the saccharine liquid, and pressed in the second mill. The weak liquid from the diffusers is re-heated and used in the diffusers for fresh bagasse. The diffusion process is universally used in making sugar from beet, and is fully described later.

Preparing the Cane. Various methods have been suggested for preparing the sugar cane for the mill, such as shredding and cutting up the cane. The Ross apparatus cuts the cane into four-inch lengths; then slices the pieces and passes them on to the mill. The Fletcher machine, for a similar purpose, was patented in 1894, and can be regulated to secure a product of the desired degree of fineness. These machines are suitable for preparing cane for the diffusion process.

The cane juice is next strained through a series of wire-gauze screens to remove pieces of cane and other mechanical impurities.

Clarification. The strained juice is then submitted to the *clarification*, or *defecation*, process. The juice is run into a large copper vessel heated by steam, and raised to a temperature of 130° F. Milk of lime, in the average proportion of 4 oz. of quicklime to a gallon of juice, is then added, and the heat continued until a temperature of 180° F. is reached. At this temperature a thick scum rises; and when the scum shows signs of "cracking" the steam is turned off. The juice is allowed to rest, and the intermediate layer of clear juice drawn off into an evaporating apparatus. The scum and sediment are transferred to a separate tank. The lime is used to neutralise the natural acids of the



3. SUGAR CANE MILL
(A. & W. Smith & Co., Ltd., Glasgow)

juice, which, if allowed to remain for any length of time, would cause inversion of the sugar.

The heat removes the albuminous matters by causing coagulation, and the lime assists mechanically and chemically in removing the coagulated albumin as scum or sediment. The process of adding lime is called *tempering*; and as the quantity to be added varies, the lime is added until a faint alkaline reaction is indicated by means of litmus paper. Various modifications of the lime process are practised, with the object of producing a whiter sugar — lime bisulphite, sulphurous acid, and "Newlanite" (phosphoric acid absorbed by kieselguhr). It is at this stage that special treatment results in the production of the yellow crystals known as *Demerara*, the procedure being really very careful tempering, combined with the addition of sulphuric acid. A tin-salt is sometimes used for the purpose, but its use should be discouraged. Aniline dyes are also inadmissible.

Continuous Defecation. Of late years continuous methods of defecation have been devised. Harvey's apparatus is a trough-like vessel heated by steam. Adjustable baffle plates or transverse divisions are fitted at spaced distances within the defecating vessel, forming practically separate chambers, while a settling chamber is fitted at the end of the defecator. Channels are arranged to draw away the scum and clear juice. By adjusting the temperature a continuous movement is given to the liquid, which readily parts with suspended matter in the settling chamber. In Deeming's superheat clarification method the juice is heated in successive stages to a high temperature, and is thence passed to a special form of settling tank. This tank is a large cylinder with a conical bottom, and inside this is a tapering vessel that reaches down to the conical part of the cylinder. The hot juice is conducted into the outer tank, and causes currents of juice which induce the sediment to fall into the conical bottom of the cylinder, the clear liquid being drawn off at the top.

The scums which have been yielded by the defecation process have steam blown into them, still further to coagulate the albuminous matter, and are then filtered, lime being sometimes added to assist the process.

Carbonatation. An alternate process of clarifying cane juice is known as *carbonatation*. The method is always used in beet sugar manufacture, and is described at a later stage. The advantage claimed for the process in the case of cane sugar is that the resulting produce is purer and fetches a higher price than sugar submitted to the usual defecation process.

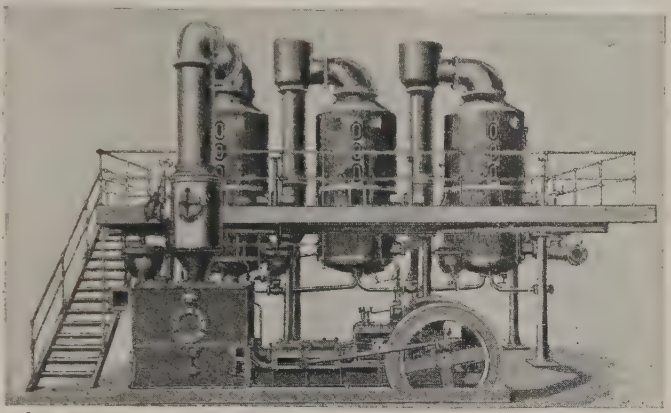
Concentrating. The next step in the manufacture of sugar is to remove the water from the clarified juice so that the sugar may be obtained in a solid state. Usually this is done by evaporating the liquid until it reaches the syrup stage, when it is transferred to a vacuum pan, and concentrated until only 5 or 6 per cent. of water is left in the mass. The oldest method of evaporating the water from the sugar is effected by using a series of pans known as the *copper wall*, consisting of a series of open pans called *teaches*, or *taches*, placed over a flue.

The open fire has now been replaced by steam-pipes in the pans. This led to what are called *film evaporators*, or *wetzels*, which expose a thin film of liquid to the action of heat. The earlier patterns consisted of a cylinder heated by steam, revolving in a trough of sugar juice. This gave place to the Wetzel evaporator [1], in which the cylinder was replaced by a number of copper pipes. The steam passes through the pipes from one end to the other the apparatus revolving in a trough of juice.

The Concretor. Fryer's concretor is a more economical method of applying heat to the evaporation of water. The object in the concretor is to pass a shallow stream of juice over a series of trays heated by an open fire or steam. The trays are divided by ribs running from one side

nearly to the other, so that the liquid requires to take a narrow, winding course during its passage from one end of the apparatus to the other. One of the concretors consists of a series of ten trays, measuring about 48 ft.; and with the serpentine course which the juice must needs take, five or six times this length is traversed, and this in about five minutes. On leaving the last tray the juice is run into a trough with a revolving cylinder heated in its interior by hot air. The heating in this part of the apparatus is continued until the mass becomes flaky instead of liquid, when it is discharged into casks, where it solidifies, and is ready for the refiner. The whole process takes about half an hour, and the average yield of concrete is about 2 lb. to the gallon of juice.

Evaporation Under Reduced Pressure. Howard, in 1813, patented a method of evaporating sugar by what are known as *vacuum pans*, which it will be convenient to refer to here. He found that by reducing the atmospheric pressure by pumping out the air from a covered pan, solutions of sugar boil at a much lower temperature, and thus no risks were run of injuring the sugar by over-heating. Further, the process was more rapid, as, owing to the lowering of the boiling-point of the liquid, the difference in temperature between the heating steam and the boiling liquid is greater, and hence greater transmission of heat is obtained for a given heating surface. The heating of Howard's vacuum pan was effected by means of a steam-jacket, but this was afterwards replaced by steam-coils within the pan. Roth introduced the use of steam-pipes, and Degrand endeavoured to utilise the vapours of the pan for heating a further quantity of liquid.



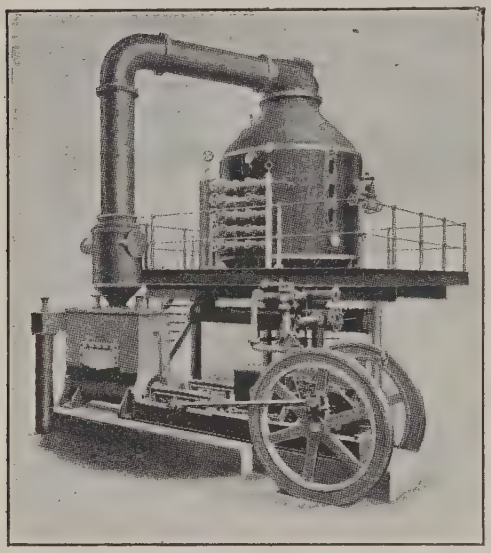
4. TRIPLE EFFET APPARATUS (Harvey Engineering Co., Ltd., Glasgow)

Multiple Evaporation. This plan of Degrand's was further developed by Rillieux, who designed a series of three vacuum pans, which he called *triple effet* [4]. The vessels are connected by means of valves, so that the juice can be drawn successively from one to the other, but the most important principle is that involved in using the latent heat of steam three times over. Dr. J. Lewkowitch explains the principle of the multiple effet as follows: "Suppose," he said, "we have at our disposal heating steam of what is termed in practice *half an atmosphere* (or one and a half atmospheres expressed in absolute pressure), such as the exhaust steam from an engine. The temperature of such steam would be about 112° C. Suppose, further, that we have employed the best practical means for producing vacuum at the outlet of the third vessel, so that the temperature would be about 46° C. We have, therefore, a temperature difference of $112° - 46° = 66°$ C. available for evaporating purposes. This difference would have to be distributed over the three vacuum vessels or effets. If we make the heating surface of each vessel the same, it follows that the amount of water evaporated will be the same in each vessel. Consequently, the difference of temperature in the three vessels must be the same—$66 \div 3 = 22°$ C. We have now the following state of affairs: the steam entering the first effet has a temperature of 112° C. We require 22° C. for raising the liquor in the first vessel to the boiling-point; the liquor would then have a temperature of $112° - 22° = 90°$ C., and the vapours escaping from the outlet the same temperature of 90° C. To this temperature of the vapour corresponds the absolute pressure of 525 mm., or, in technical parlance, a vacuum of 235 mm.—say, 9 in. A gauge (*manometer*) fixed to the outlet of the first vessel would therefore register this vacuum. The steam enters the heating system of the second effet with a temperature of 90° C. The liquid in the second vessel requires 22° for raising it to the boiling-point, and has therefore the temperature of 68° C. If no loss of heat takes place, the temperature must be slightly higher, as the flow of liquid goes in the direction from the first effet to the second effet, and the liquid coming from the first vessel has the temperature of 90° C., but this point may be neglected here. The vapour escaping from this second vessel will have the temperature of 68° C., which corresponds to an absolute pressure of 213 mm. (8·5 in.) or a vacuum of 547 mm.—say, 21·5 in. This vapour of 68° C. enters the heating chest of the third vessel, and brings the liquid therein to the temperature of 46° C."

The Yaryan Evaporator. Rillieux, the inventor of the system of multiple evaporation, employed horizontal cylinders furnished with a number of horizontal tubes. A disadvantage is that the steam passes through all the heating tubes with a uniform velocity, very low in the case of the second and third effets, thus making a rapid exchange of heat impossible. This led to the use of vertical vessels with shorter horizontal heating tubes, such as are now employed. The next innovation was Yaryan's, in which the liquid is passed through narrow tubes while the steam circulates around them. Yaryan adopts in his apparatus [2] the two principles of evaporation in *vacuo* and multiple effet. The evaporator consists of a series of straight tubes passing from end to end of a shell or drum, and coupled together by an ingenious arrangement of pockets to form coils, the main advantage gained being the ease with which the straight tubes can be examined and cleaned.

Lille's Evaporator. This apparatus introduced in 1893, has for its object the separation of suspended liquid particles from the vapours evolved during the evaporation of liquids. By means of perforated plates the juice is distributed over a series of horizontal pipes arranged in a

closed chamber. Steam is circulated through the pipes. The vapour from the juice passes through and around baffle plates into a prolongation of the evaporating chamber called the subsiding chamber. The baffle plates cause the suspended particles to separate and fall to the bottom of the subsiding chamber, whence they are drawn off by means of a pipe below. The vapour passes off by an outlet



5. THE VACUUM PAN
(A. and P. W. McOnie, Glasgow)

pipe in a dry state, the pipe being in the upper part of the subsiding chamber.

Harvey's Evaporators. Patented in 1899, these evaporators are constructed of a series of steam-pipes with vertical juice-circulating tubes and vapour-generating vessels which are superposed in vertical columns so as to act as triple or multiple effet. Rapid circulation of the juice is attained, and a quick rate of evaporation.

There are numerous other varieties of evaporator, but each will be found to fall within one of the general kinds enumerated above.

Crystallising. In the copper wall, Wetzel apparatus, and Fryer's concretor, the juice is converted into solid sugar, while in the multiple effet and Yaryan evaporator the juice is only reduced to a syrupy consistence—until it has lost 70 per cent. of its bulk. When the juice has reached this stage it is transferred to a *vacuum pan* and boiled until grains of sugar are formed. The vacuum pan [5] is fitted with two or three coils [6] of steam-pipe sufficiently separated to allow of free circulation of the contents of the pan. The pan is fitted with pumps for making a vacuum, and a contrivance called a *proof-stick* for obtaining samples of liquid from the interior without breaking the vacuum. The working of the vacuum pan is as follows: The air-pump is started, and as soon as the vacuum reaches 26 in. or 27 in. the feed cock on the side of the pan is opened, and sufficient liquor drawn in to cover the bottom coil. Steam is then turned into the coil, and the liquor rapidly evaporates. Further supplies of liquid are admitted at short intervals, the feed cock being opened for about fifteen seconds at a time until the contents of the pan show signs of "graining," when samples are taken with the proof-stick. The grain is "fed" carefully, the cock being opened frequently, and each time the quantity admitted increased. As the amount of syrup in the pan increases, steam is turned on in the other coils, until at the completion of the charge the pan is nearly full, or up to the "bull's eye" or sight-hole in the side of the pan. In this way the grain "grows" in size. The whole skill of the pan-boiler consists in inducing the grains to grow to their utmost, and this can only be done very slowly and by manipulating the temperature.

Striking the Pan. The mass in the pan at the finish of the boiling is termed *massecuite*, and the operation of discharging or emptying the pan is known as *striking*. The striking-point is judged by the firmness of a sample taken from the pan and suddenly cooled in water. When the grain is very small the pan is sometimes only half emptied, and fresh syrup admitted, the half-emptying process being known as *doubling*, and the discharged massecuite as *first cut*. The process with pure juices can be repeated several times, but a point is reached at last when the crystals do not increase in size, and the whole charge is *struck*. To save time in boiling it is now general to add sugar grains to the pan instead of forming grain from the syrup, this being known as *seeding*. In a pan containing about thirty tons of massecuite, one ton of sugar is required, the sugar used being that recovered from the molasses.

Curing the Sugar. The massecuite from the last operation consists of a mixture of crystalline sugar and molasses. The problem now is to separate the two. The oldest method is to run the massecuite into coolers, and, when set, to dig out the mass and put it into casks with perforated bottoms. In this way the molasses is drained out partially and yields raw or *muscovado sugar*. This crude method has been replaced in most countries by treatment of the massecuite in centrifugals. This process and crystallisation in motion which now accompanies it is dealt with later in connection with refining.

The recovery of sugar from molasses is dealt with after a consideration of beet sugar, as the processes are common to the manufacture of cane and beet sugar.

6. LYRE-SHAPED TUBES IN VACUUM PAN

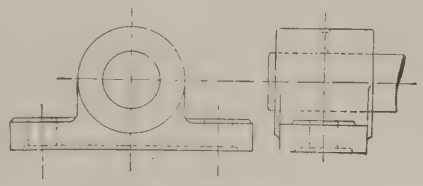
Cane Sugar Factory. A factory capable of dealing with 100 tons of cane per twenty-four hours, and employing engines of 150 h.-p., turning out eight tons of sugar daily, could be erected and equipped for about £40,000. The cane mills are placed on the ground floor, and the juice is pumped up to the top floor, and descends as it is manufactured. In the laboratory a *polariscope* and a balance are required, as well as dishes and other pieces of apparatus. The establishment of central factories has been urged as a means of assisting the sugar industry in the West Indies. A factory in which modern machinery and scientific control are installed would be able to obtain a better yield of sugar than smaller factories. In buying sugar cane the sugar-yield is the only satisfactory basis.

Technical Drawing. Deadeyes. Adjustable Bearings.
Waggon Axle-boxes. Babbitt Bearings. Brackets. Hangers.

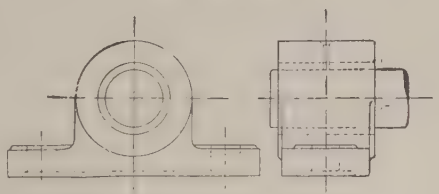
BEARINGS AND AXLE-BOXES

Bearings. The simplest form of bearing for a shaft journal is illustrated in **55**, and consists of a metal boss having a foot cast with it for convenience of bolting down ; such a bearing is termed a "deadeye." It is chiefly used for slowly revolving shafts of hand-driven appliances ; when wear takes place it is necessary to renew the bearing itself. Fig. **56** shows a similar deadeye fitted with a renewable gun-metal sleeve, or bush, which is forced into place, and can be replaced when worn. Alternatively, such plain or bushed bosses may be designed as part of a machine framing instead of being separate pieces. A great drawback to the use of these bearings is the necessity for parallel shafts, and the inconvenience of removing all objects keyed thereon in order to get the shaft out of the bearings, for it must obviously be moved endwise.

Divided Bearings. The divided brass and adjustable cap are illustrated in **58**. They have not only the advantage of being renewable, but by taking off the cap piece and one half of the brass the shaft may be removed bodily ; the bearing is also adjustable by the tightening of the cap bolts and the consequent closing of the brasses when wear has taken place. The cap is secured by studs and lock nuts ; the brass has pegs cast on it which enter corresponding holes in the cap and seating in order to prevent turning ; flanges are provided at each end to take the thrust of collars, etc., on the shaft. These bearings may be arranged as part of a machine frame or alternatively as a separate article. Fig. **57** indicates it in this latter form, when it is termed a *plummer block, or pedestal ;* the cap bolts pass through the block, and have square heads fitting in square holes ; the base of the block has facing strips provided, which facilitate the fitting of the pedestal in its place.



55. DEADEYE



56. DEADEYE WITH BUSH

The proportions for **57** and **58** may be taken as follow :

Thickness of brass	$B = \cdot 1A + \cdot 15$ in.
Thickness of flange	$C = B$
Length of turned portion	$D = 1 \cdot 7\ B$
Diameter of peg	$E = B + \frac{1}{4}$ in.
Thickness of cap	$F = \cdot 4\ A$
Thickness of cap	$G = \cdot 38\ A$
Centres of cap bolts	$H = 1 \cdot 8\ A$
Diameter of cap bolts	$I = \cdot 25\ A + \frac{1}{4}$ in.
Height of block above centre	$J = \cdot 4\ A$
Height of block base to centre	$K = 1 \cdot 5\ A$
Thickness of base	$L = \cdot 38\ A$
Centres of base bolts	$M = 2 \cdot 75\ A + 4$in.
Diameter of base bolts	$N = \cdot 25\ A + \frac{1}{4}$ in.
Length of base	$O = 3 \cdot 5\ A + 5$ in.
Length of bearing	$P = 1 \cdot 75\ A$

The brasses need not necessarily be circular in outside formation ; in fact, many of the earlier types of bearings had hexagon-shaped exteriors. A good form is shown in **59**, where the brass is square on the outside, and fits into a square block, the cap being made of mild steel ; the whole bearing is bolted to the steel side-frame of a heavy steam crab. This example is taken from an actual working drawing.

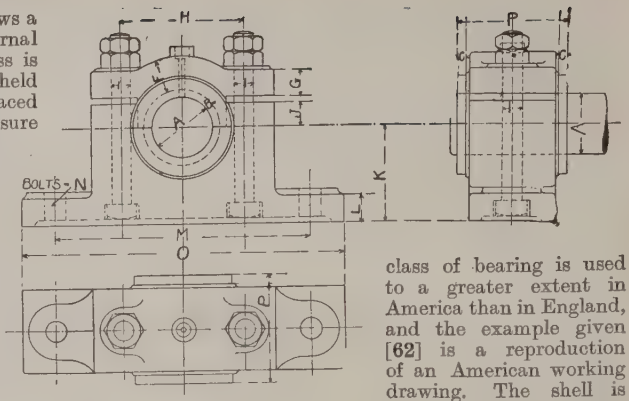
Adjustable Swivel Bearings. A modern form of bearing used largely for line shafting is illustrated in **60**. It consists of a cast-iron bearing divided on the centre line and held together by square threaded screws at the top and bottom ; the ends of these screws have concave heads which fit over corresponding convex projections on the central part of the bearing. The bearing is thus free to swivel radially, and at the same time can be adjusted in a vertical sense by means of the screws which can be rotated with a bar inserted in the holes of their bosses. The screws can be locked in position by set screws, as shown in the main bracket. The shape of the bracket varies considerably, according to requirements ; the one shown [**60**] is arranged for bolting up to a wall or column, but can easily be designed in the shape of the letter J, so as to bolt up to a ceiling joist or beam. The proportions may be taken as follow :

Length of bearing, if cast iron	$B = 4\ A$
Length of bearing, if brass	$B = 2\ A$
Distance between bosses	$C = A + \frac{1}{2}$ in. $\times 2 \cdot 75$
Depth of boss	$D = A + \frac{1}{2}$ in.
Diameter of boss	$E = A \times 1 \cdot 8$
Diameter of screw	$F = A$

Lubrication is effected by means of the two oil holes, which are fitted with lubricators ; sometimes an oil tray is suspended underneath the bearing to catch the waste oil. In the case of the shorter brass bearings the screw is made hollow, and lubrication is thus readily effected through the centre.

Railway Axle-boxes. Another type of bearing is the railway axle-box, which has several unique features not found in ordinary bearings. The brass does not embrace the whole circumference of the journal, nor does it extend the full length. The load always comes on the brass in a vertical sense, and there is therefore no necessity for a lower half brass, its place being taken by a device known as a "keep," which prevents undue vertical play between the journal and the brass. When a train is travelling at a high speed or passing round a curve there is considerable movement sideways, which must be allowed for in the axle-box, otherwise the continual side thrusts would destroy it. Lubrication is also a most important factor to be arranged for.

Waggon Axle-box. Fig. 61 shows a standard waggon axle-box having a journal $3\frac{3}{4}$ in. diameter by 8 in. long; the brass is $2\frac{1}{2}$ in. wide by $7\frac{7}{8}$ in. long. It is not held in place by fastenings, but is simply placed in a recess, and kept there by the pressure of the load transmitted to the journal. End movement of the brass is prevented by the shoulders formed upon the central portion. The axle keep is simply a $\frac{7}{8}$-in. diameter bolt. The top of the box is made with a rectangular recess for the reception of the bearing spring, which has a small clearance all round to allow for play. The whole box is guided in horn plates, and definite clearance is also allowed here. The chamber between the brass and the spring seat is filled with grease, which melts as the bearing becomes slightly warmed, and passes through the two holes which lead to the journal, and by such means a plentiful supply of lubricant is assured. A wooden shield is fitted to a shallow chamber at the inside end of the box in order to keep out dust and dirt. The views illustrated comprise a longitudinal section of the box and brass, showing the journal in external elevation, the dust shield and the grease door being also shown in section; a half transverse section, AA, through one of the oil holes shows the shoulder on the brass, which prevents its end movement; a half transverse section, BB, on the centre line; a half plan; a half sectional plan; and two views of the brass.

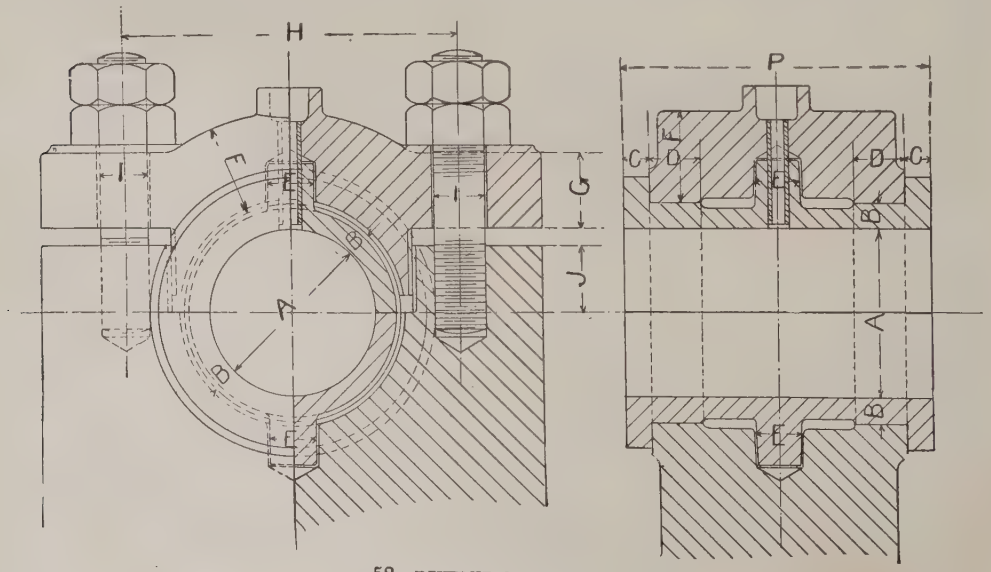


57. PLUMMER BLOCK

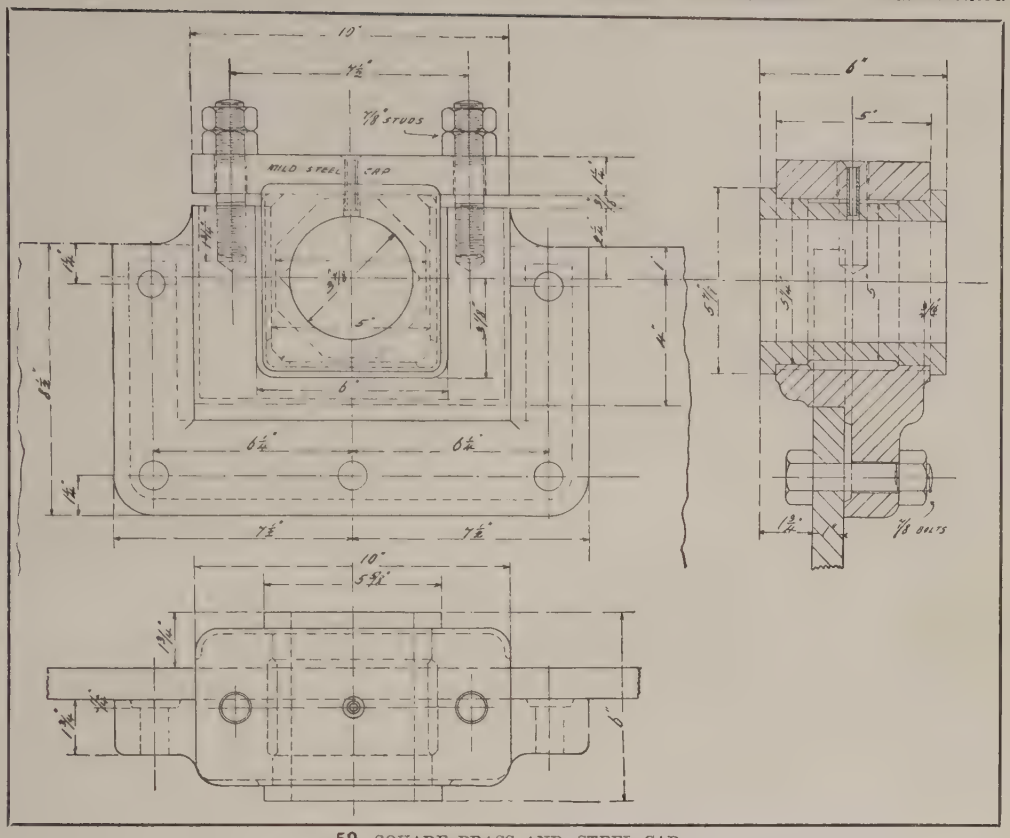
Carriage axle-boxes and those for locomotives differ in some details from the waggon boxes, but the general type is retained.

Babbitt Bearings. Brass and bronze are not the only metals which are used for bearings; various fusible alloys are also available, but are used as linings only, a removable shell being employed to carry them. Fig. 62 illustrates a shell lined with Babbitt metal, which is an alloy of tin, copper, and antimony; the shell may be either of brass or of cast iron, with recesses as shown to prevent movement of the lining; this class of bearing is used to a greater extent in America than in England, and the example given [62] is a reproduction of an American working drawing. The shell is somewhat thinner than an ordinary brass bearing, and is machined all over to bear its full length in the pedestal or seating block; it is prevented from turning by a peg or dowel fixed in the pedestal, and entering the lower half of the shell. The lining is readily renewed when worn away too much to afford proper support to the journal. Babbitt and similar metals melt at a low temperature, and can be poured like type metal; to renew a lining the old one is first melted out, then a dummy shaft or mandrel is placed in the shell, and new metal poured around it.

Brackets and Hangers. It is only in the building of a machine or engine that bearings are formed or fitted direct to framings, etc. For line shafting and for bearings on structural work it is usual to have a bracket between the bearing and its eventual support. Fig. 63 shows a plummer block fitted to a bracket, which has feet at right angles to the foot of the block, and is suitable for bolting to a wall or a column; the block might be cast in one piece with the bracket, but when made separately, as shown, it is readily adjustable horizontally and vertically; the bolt holes in the base of the pedestal are slotted, so that the block may be adjusted laterally; hardwood or steel



58. DIVIDED BEARING



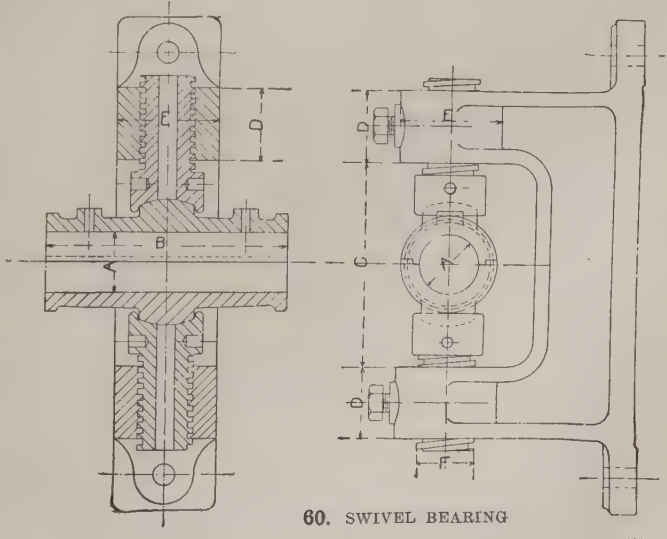
59. SQUARE BRASS AND STEEL CAP

wedges are then driven in at the ends. If vertical adjustments are required, a liner may be placed between the base of the pedestal and the bracket.

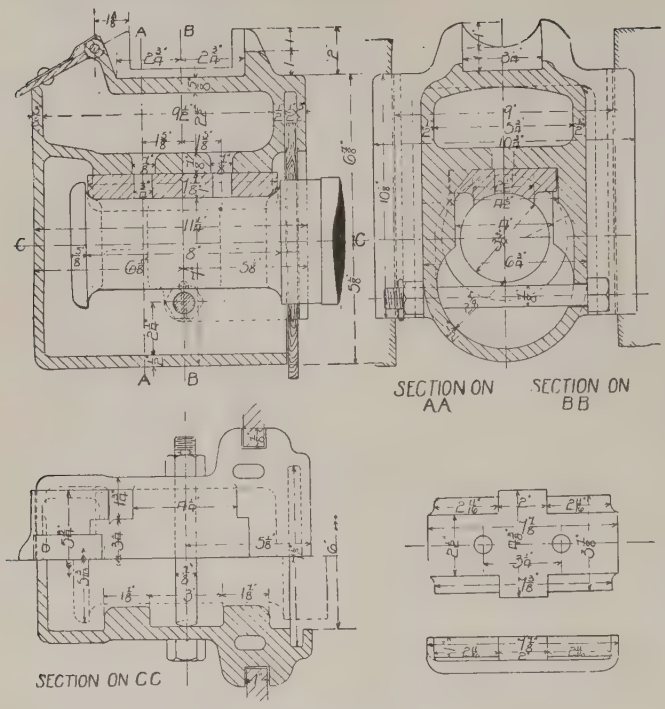
Fig. **71** illustrates a hanger suitable for suspending a pedestal from a ceiling or roof girder; the block is adjustable in the same manner as in the previous example. The dimensions of **63** and **71** are found by multiplying the figures given on the drawings by A + ½ in. where A = diameter of shaft; the over-all dimensions are, of course, modified to the local conditions.

There are many bearings which may be classed as special, such as footstep bearings, thrust bearings, roller bearings, ball bearings, heavy crank shaft bearings, etc.

Thrust Bearings. The most efficient thrust is that made with steel balls, for in such construction rolling friction takes the place of sliding friction. Fig. **64** illustrates a ball-thrust bearing arranged at the bottom end of a vertical spindle. This is made by the Hoffmann Manufacturing Co., Chelmsford. The construction is simple and entirely self-contained; the baseplate F can be made to suit any machine, or it may be part of a machine. The ball thrust proper is composed of an outer cast-iron casing, G, recessed into the baseplate, F; a cone or floating disc, H, which automatically adjusts itself in its seating and so ensures an equal load upon all the balls; a ring of balls held in a retaining cage, I, a hardened steel cup, K, and a retaining wire, L. The retaining cage I prevents any friction between the



60. SWIVEL BEARING



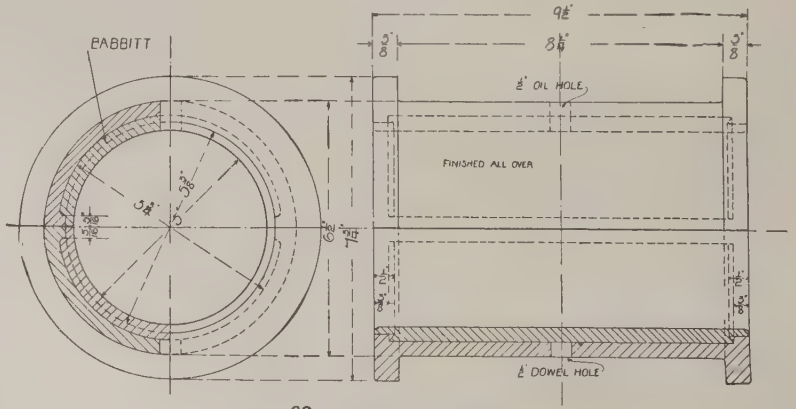
61. WAGGON AXLE-BOX

balls themselves; it is so designed as to float upon the balls, and therefore it does not bear upon either the cup K, the cone H, the casing G, or upon the spindle itself to cause friction. The retaining cage also enables the complete ring of balls to be handled without the balls falling out, a great convenience when putting a bearing together or dismantling. The retaining wire L keeps all the parts together. It is not necessary to key either the cone H or the cup K in place, as the friction between them and the balls is so slight that the friction between them and their seats is ample to prevent rotation. The steel balls are "Hoffmann balls," and are guaranteed to be within one ten-thousandth part of an inch of standard, both as to sphericity and size. These bearings do not provide for side support of the spindle, but only for end thrust; they are made in heavy, medium, and light types.

Footstep Bearing. An ordinary footstep bearing is shown in **66**, which provides for end thrust and also for side support of the spindle, but is not so efficient as the previous example. The thrust is taken upon a concave steel disc, A, laid upon the baseplate B, and kept from turning by the pin C; the disc A is kept in a central position by the gun-metal bush D, which bush also gives side support to the spindle; the set screw E keeps the bush from turning.

Ball-thrust Washers. A common device to take end thrust on light spindles is to have several washers arranged between the end bearing and a collar on the shaft. A better method is illustrated in **65**, which shows an application of two Hoffmann ball-thrust washers to the feed screw of a lathe slide. The ring of balls is held in a retaining cage, as in **64**; hardened steel washers are provided for the balls to run between; these bearings are made with a hole five-thousandths of an inch larger than standard, so as to allow the spindle to revolve freely inside the washer. The end of the spindle is screwed and fitted with a circular nut, which is kept from revolving by a pin which passes through both nut and spindle.

Ball-bearing Hubs. A good example of a ball bearing which takes both end pressure and journal pressure is shown in **68**. It is known as the Hoffmann patent *ball-bearing hub*, and is specially designed for motor-cars and vehicle wheels of all kinds. There are four rows of balls in each hub: the two outer rows take the journal load, while the two inner rows take end thrust in either direction. The load is taken in each case at right angles to the axis of rotation of the ball, and a perfect rolling action is attained with a consequent minimum of friction. The cone piece is of hardened steel ground out internally to a taper which fits the axle and is held on by a nut and pin in the usual manner. When this nut is removed, the wheel, with the bearing complete, can be taken off the axle. The removal of the wheel with bearing does not interfere in any way with the adjustment of the ball bearings. When it is required to dismantle the bearing, it is done

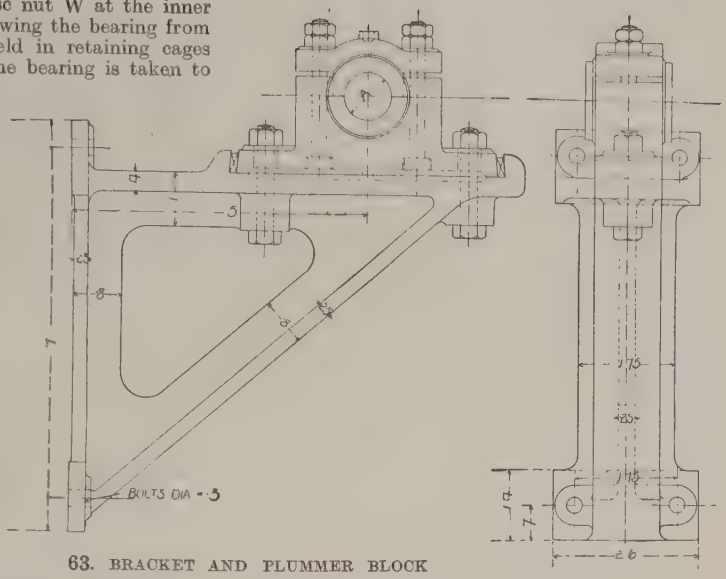


62. BABBITT BEARING

easily by unscrewing the disc nut W at the inner end of the hub, and withdrawing the bearing from that end. The balls are held in retaining cages and do not fall out when the bearing is taken to pieces. Leather washers are fitted to the disc nut in order to exclude dust.

The use of ball bearings as a means of reducing friction between moving parts has wide applications, apart from the examples given, but the principles of design and construction do not materially alter.

Roller Bearings. Another anti-friction appliance is the roller bearing, the underlying principle of which is identical with the ball bearing—that is, the substitution of rolling friction for sliding friction. Bearings are made having solid rollers interposed between the shaft and its seating; such bearings when properly designed are a great improvement on plain bearings having sliding friction, but they are not perfect. To obtain the best efficiency and the longest life out of a roller bearing the rollers must be flexible, so as to present even bearing surface along their entire length. The irregularities incidental to the running of shafting and axles prevent the uniform distribution of load over the full length of the bearing, resulting in unequal wear and distortion of the rollers when they are made solid, and consequently rigid. There are several methods of making rollers flexible, one of the best of which is adopted in the Hyatt *flexible roller*. This roller is made from a strip of steel wound into a coil or spring of uniform diameter; it is applicable to all speeds and loads, and can be made of thin material for light loads and high speeds, and of thicker material for heavy loads and slow speeds. The roller acts as an oil reservoir and the spiral grooves as oil carriers. If dirt or other foreign matter get into the bearing it is squeezed into the inside of the roller away from the bearing surfaces.



63. BRACKET AND PLUMMER BLOCK

Eccentric Bearing. Fig. 67 shows an application of the Hyatt flexible roller. It is a drawing of the eccentric bearing of a cotton gin. The bearing is not concentric with the shaft, but the centres are $\frac{3}{4}$ in. apart, which gives a reciprocal throw of $1\frac{1}{2}$ in. to the socket A. This movement is virtually a cam action, and is carried out at the high speed of 1000 revolutions per minute. The eccentric B has a split-steel sleeve fitted to it, this being ground to give a true and hard bearing surface for the rollers. A similar sleeve or lining is fitted inside the strap C. The rollers lie between the sleeves, and are kept in place by a retaining cage, which holds them in such a way as not to restrict their operation, but simply to prevent them from getting too far out of line. The split sleeves are shown in detail, and they are kept from turning by pins as indicated in the general views. The strap C is in halves to facilitate removal, and it has bronze end-plates fitted. The bearing is kept flooded with oil.

Waggon Bearing. A unique yet entirely successful application of the Hyatt roller is given in 69, which is a copy of a working drawing.

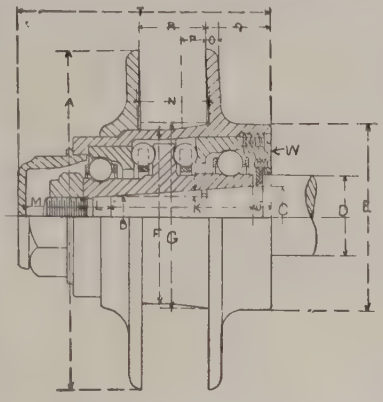
67. ECCENTRIC ROLLER BEARING (Hyatt Roller Bearing Co., Ltd.)

It represents a waggon axle-box as made for the North-Eastern Railway Company. The journal is 5 in. diameter and 9¼ in. long; the end of the axle is reduced in diameter, and a steel ring is shrunk in order to keep the sleeve in place. The outer and inner sleeves are split and ground true as in the previous example; the rollers are kept in a retaining cage. A bronze thrust block is fitted in the end cover of the box, and also an oiling ring to ensure the lubrication of the thrust block. The external arrangement of the box is normal; there is the usual dust-guard at the inner end, and the usual formation of spring seat on the top. The box has grooves for double horn plates, as shown. This bearing after being in use for a twelvemonth was still in perfect condition. This class of bearing is widely used in a lighter form for small cars and mine trucks, and very frequently in such cases the wheels are loose on the axles and contain the roller bearing in their bosses.



68. BALL-BEARING HUB

Swivel Bearing. Great saving in power is effected when roller bearings are applied to line shafting. Fig. 70 illustrates the construction of one fitted to such a bearing as is shown in 60 on page 5527. The construction is generally as the preceding examples, but the inner sleeve is omitted. Small metal wipers are fitted at each end to prevent oil from creeping along the shaft, and so getting outside of the bearing. Such a bearing is suitable for high-speed shafting. The scope of the Hyatt flexible roller is much wider than the examples we give. In motor-car work alone it is used very extensively.

Belt Driving. Belts are used for transmitting power from line shafting to machines by means of pulleys; power may also be taken from an engine or a dynamo to shafting by belting and pulleys. Driving belts are usually made of leather, but other materials, such as camelhair, cotton, and indiarubber, are successfully employed, and in some situations are superior to leather, as they are

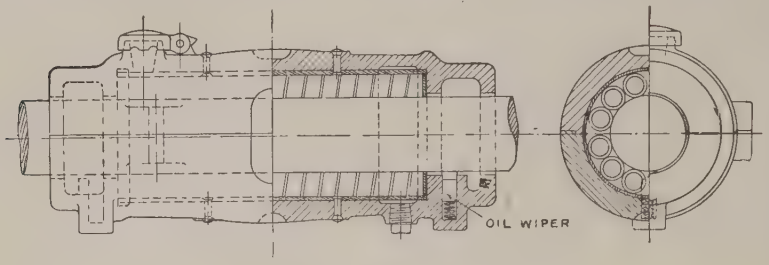
69. WAGGON ROLLER BEARING (Hyatt Roller Bearing Co., Ltd.)

less affected by damp, chemical fumes, etc.; in the case of the camelhair belting, there is less slip between the belt and the pulley, and consequently a better driving effect is obtained. Leather belts are made from the best portion of ox-hides. The amount that can be utilised from an average hide is about 4½ ft. long by 4 ft. wide, and is termed the "butt." The thickness is about $\frac{2}{16}$ in. to ¼ in.; the ultimate strength of the prepared leather is about 3500 lb. per square inch, but this cannot be taken full advantage of in a belt, on account of the jointing which is necessary. If due allowance be made for the laced joint and for a reasonable margin of safety, 350 lb. per square inch may be taken as a safe working load. In calculating the size of a belt for a particular duty it is more convenient to figure the load in lb. per inch of width of belt; 350 lb. per square inch is equal to 66 lb. per inch of width if the belt be in. $\frac{3}{16}$ thick, or 78 lb. if the belt be ¼ in. thick. Double belts are made by cementing two strips of leather together in a superimposed position; they are then sewn or riveted; the resulting thickness is ⅜ or ½ in., as the case may be. Such belts have not quite double the strength of single belts, nor do they drive quite so efficiently, and as they are not so flexible they cannot be used on small pulleys; a 30-in. diameter pulley is quite small enough for a double belt to drive properly.



70. SWIVEL ROLLER BEARING

Speed and Power of Belting. The speed of belting varies according to the work it is designed to do; lathes and machine tools have a belt speed of 1000 to 3000 ft. per minute, line shafting may go up to 2500ft. per minute, main drives from engines up to 4000 ft. per minute; some belts run above this latter speed, but no material advantage is gained thereby. The speed of a belt is easily calculated from the diameter and speed of the pulley. The rule is: Multiply the diameter of the pulley by 3·1416, and by the number of revolutions per minute of the shaft. Example: a shaft revolves at 150 revolutions per minute, driven by a pulley 36 in. diameter, the speed of the driving belt is 36 by 3·1416 by 150 = 1414 ft. per minute. A slight inaccuracy, however, is here to be noticed; the speed calculated above is the theoretical speed of the rim of the pulley. Now, a belt "slips" to a certain extent upon the face of the pulley, and by that amount lags behind the speed of the pulley. The usual amount is 1 per cent., so that the actual belt speed in the case above figured out would probably be 1400 ft. per minute.

Power is transmitted from a belt to a pulley or vice versâ by frictional contact, and it therefore depends considerably upon the arc of circumference embraced; if the arc of contact be increased or decreased, so the grip of the belt upon the pulley is increased or decreased, and the driving effect varied accordingly. This is very important to note when designing belt drives. The whole subject of belting is treated exhaustively on page 3848.

Agreement of the Verb with the Subject.
Use of Auxiliaries and the Subjunctive.

FRENCH

Continued from page 5415

By Louis A. Barbé, B.A.

VERBS

Agreement with a Simple Subject

1. Every verb in a finite tense agrees with its subject in number and person: *Le cœur d'une mère est le chef-d'œuvre de la nature,* A mother's heart is Nature's masterpiece.

2. When a verb has for its subject a collective noun, or noun of multitude, followed by another noun in the plural as its complement, that verb is in the singular or in the plural, according as the leading idea is expressed either by the collective or by its complement: *Une nuée de sauterelles obscurcit l'air,* A cloud of locusts obscured the air; *Une nuée de barbares désolèrent le pays,* A cloud of barbarians laid waste the country.

3. After *la plupart,* whether a plural complement is actually expressed or only understood, the verb is always in the plural: *Quand on en vint aux voix, la plupart se déclarèrent de mon avis,* When it came to voting, the greater number declared themselves of my opinion.

4. After the adverbs of quantity, *peu, beaucoup, moins, assez, trop,* followed by a plural, the verb is always in the plural: *Beaucoup de gens promettent; peu savent tenir,* Many people promise; few know how to keep (their promises).

5. When *peu* is preceded by *le,* the verb is in the singular if *le peu* expresses want or deficiency: *Le peut de gens avec qui on peut communiquer des sciences abstraites m'en avait dégoûté,* The few (= the lack of) people with whom one can discuss the abstract sciences had put me out of conceit with them.

When *le peu* expresses a small quantity, or a small number, the verb agrees with the noun following it: *Le peu d'amis que j'avais sont venus à mon secours,* The few friends I had have come to my help.

6. *Plus d'un,* though expressing plurality, requires the verb that follows it to be in the singular: *Plus d'un doit son succès à sa persévérance autant qu' à son talent,* More than one owes his success to his perseverance as much as to his talent.

7. The verb of which *tout le monde* is the subject is always in the singular: *Tout le monde est sujet à l'erreur,* Everybody is liable to error.

8. When preceded by *ce,* the verb *être* is in the third person singular if it is followed by a plural pronoun of the first or of the second person, or by two or more nouns in the singular: *C'est nous qui avons le plus souffert de sa tyrannie,* It is we who have suffered most from his tyranny.

9. Though preceded by *ce,* the verb *être* requires to be in the plural; if it is followed by a plural noun or by a personal pronoun in the third person plural: *Ce furent les Phéniciens qui inventèrent l'écriture,* It was the Phœnicians who invented writing.

10. When the verb *être* preceded by *ce* is followed by two (or more) substantives of which one is singular and the other plural, it takes the number of the substantive nearest to it: *Ce sera le même théâtre et les mêmes décorations.* It will be the same theatre and the same decorations.

11. When the verb *être* preceded by *ce* is equivalent to the impersonal verb *y avoir,* it may, if followed by a plural noun, be either in the singular or the plural itself: *C'était* (or *c'étaient*) *tous les jours de nouvelles plaintes,* There were new complaints every day.

12. The verb *être* preceded by *ce* remains in the singular if it is followed by a noun and a numeral adjective which, though plural in form, convey an idea of unity, and may be replaced by the singular: *C'est quatre heures qui sonnent,* It is four o'clock that is striking—that is to say, *la quatrième heure,* the fourth hour.

Agreement with Several Subjects

1. When the subject of a verb consists of several nouns or pronouns in the singular, the verb itself is in the plural: *L'hirondelle et le rossignol annoncent le retour du printemps,* The swallow and the nightingale announce the return of spring.

2 When the various parts of the subject are not of the same person, the verb is in the plural and agrees with the person that has priority. In that case, it is usual, but not essential, to introduce an additional plural pronoun representing that person: *Vous et moi (nous) sommes contents de notre sort,* You and I are content with our lot.

3. The verb may be in the singular when the various nouns of which the subject consists are practically synonymous.

4. When two subjects are joined either by *ni* or by *ou,* the verb is usually in the plural, unless it is obvious that one subject excludes the other: *Ni l'or ni la grandeur ne nous rendent heureux,* Neither gold nor greatness make us happy. *Ni Corneille ni Racine n'est l'auteur de ces vers,* Neither Corneille nor Racine is the author of those verses.

5. A verb having *l'un et l'autre* for its subject must be in the plural: *L'un et l'autre rapportent les mêmes circonstances,* The one and the other (= both) record the same circumstances.

Complement of the Verb

1. The same noun may be the complement (or object) of two verbs, provided both verbs govern the same case: *Les enfants doivent aimer et respecter leurs parents,* Children should love and respect their parents. Here, *parents* is the direct object (or accusative) of both *aimer* and *respecter.* It is incorrect to say: *Les enfants doivent obéir et respecter leurs parents,* because *obéir* requires an indirect object (or dative), whilst *respecter* governs a direct object (or accusative). The proper construction is: *Les enfants doivent obéir à leurs parents et les respecter,* Children must obey their parents and respect them.

2. When a verb has several complements joined by *et, ou,* or *ni,* all these complements must be of the same kind—*i.e.,* either all nouns, or all infinitives, etc.; but not one noun and one infinitive: *Il aime le chant et le dessin,* He likes singing and drawing; *Il aime à chanter et à dessiner,* He likes to sing and to draw.

Both these sentences are correct; but it would be incorrect to say: *Il aime le chant et à dessiner,* He likes singing and to draw.

3. If a verb has both a direct and an indirect complement, the direct complement (or accusative) comes first, provided both are of equal length: *On doit préférer la mort à l'esclavage*, We should prefer death to slavery.

4. If the two complements are of unequal length, the shorter usually comes first: *L'avare sacrifie à l'intérêt son honneur et sa vie.* The miser sacrifices honour and life to interest.

Use of Auxiliaries

1. All transitive verbs take *avoir* for their auxiliary: *J'ai donné; tu avais fini; il aura reçu; vous auriez vendu.*

2. Most intransitive verbs take *avoir* for their auxiliary: *Il a succombé; elle avait régné.*

3. All reflexive verbs are conjugated with *être* in their compound tenses: *Je me suis blessé; vous vous seriez aperçus.*

4. The passive voice consists throughout of the verb *être* with a past participle added to it: *Il est aimé; ils ont été battus.*

5. The following intransitive verbs are always conjugated with *être*:

Aller, to go; *arriver*, to arrive; *choir*, to fall; *décéder*, to die; *échoir*, to fall due; *éclore*, to be hatched, to blossom; *entrer*, to enter; *mourir*, to die; *naître*, to be born; *repartir*, to set out again; *ressortir*, to go out again; *retourner*, to go back; *venir*, to come; and the derivatives *rentrer*, to come back, to re-enter; *devenir*, to become; *intervenir*, to intervene; *parvenir*, to succeed, to attain to; *provenir*, to proceed from; *redevenir*, to become again.

6. A certain number of intransitive verbs, though almost always conjugated with *être*, are occasionally to be found conjugated with *avoir*. They are:

Descendre, to go down; *monter*, to go up; *partir*, to set out, to go off; *retomber*, to fall again; *tomber*, to fall.

7. Any intransitive verb used transitively requires *avoir* for its auxiliary: *Avez-vous descendu nos bagages?* Have you taken down our baggage?

8. A certain number of verbs, of which the following are the chief, are conjugated with *avoir* or with *être*, according as they denote action or state resulting from action:

Accourir, to run up; *cesser*, to cease; *changer*, to change; *croître*, to grow; *déborder*, to overflow; *dégénérer*, to degenerate; *disparaître*, to disappear; *échouer*, to run aground, to fail; *embellir*, to become handsomer; *grandir*, to grow up; *grossir*, to increase in size; *maigrir*, to become thinner; *passer*, to pass; *rajeunir*, to become young again; *vieillir*, to grow old. *Cet enfant a bien grandi en peu de temps*, That child has grown a great deal in a short time. *Comme il est grandi!* How grown (= tall) he is!

9. Some verbs have different meanings, according as they are conjugated with *avoir* or with *être*. Such are, *Convenir*, to suit, to agree: *Cette maison nous a convenu*, That house has suited (pleased) us. *Nous sommes convenus d'acheter cette maison*, We have agreed to buy that house.

Demeurer, to dwell, to stop: *Il a demeuré longtemps à Paris*, He lived a long time in Paris. *L'affaire en est demeurée là*, The matter stopped there.

Échapper, to escape notice, to be forgotten, to slip from, to be said unwittingly: *Ce que je voulais vous dire m'a échappé*, What I wished to tell you has escaped me (*i.e.*, my memory). *Il lui est échappé un mot qu'il ne voulait pas dire*, A word he did not wish to say has escaped him.

Use of the Subjunctive

1. The verb of the subordinate clause must be in the subjunctive when the verb of the principal clause expresses surprise, admiration, wish, consent, prohibition, doubt, fear, command: *Je m'étonne qu'il ne voie pas le danger où il est*, I am astonished that he does not see the danger in which he is.

2. The verb of the subordinate clause must be in the subjunctive when the verb of the principal clause is either negative or interrogative: *Je n'ai employé aucune fiction qui ne soit une image sensible de la vérité*, I have used no fiction but is a sensible image of truth. *Croyez-vous qu'il vienne?* Do you think he will come?

Exception: When the interrogation is merely formal, and really amounts to a direct statement, the subjunctive is not required: *Croyez-vous que les Parisiens sont des sots?* Do you think Parisians are blockheads?

3. The verb of the subordinate clause must be in the subjunctive after impersonal verbs and phrases: *Il vaut mieux qu'il ne vienne point*, It is better he should not come. *Il importe que vous y soyez*, It is important that you should be there.

Exception: (*a*) The indicative is required after *il s'ensuit*, it follows; *il résulte*, it results; *il arrive*, it happens; and after impersonal phrases in which there occurs an adjective expressive of certainty, such as *évident, sûr, certain, vrai*, except when these are either negative or interrogative: *Il arrive souvent qu'on est trompé*, It often happens that we are mistaken.

(*b*) The verb *sembler*, though used impersonally, requires the indicative if it is preceded by one of the personal pronouns *me, te, nous, vous, lui, leur*; but, if used negatively or interrogatively, it follows the rule: *Il me semble qu'il n'y a pas de plus grande jouissance que celle de faire des heureux*, It seems to me that there is no greater happiness than that of making people happy. *Il ne me semble pas que l'on puisse penser différemment*, It does not seem to me that anyone can think otherwise.

4. The verb of a relative clause must be in the subjunctive if it does not express an actual fact, and if the relative clause implies some purpose regarding the antecedent, or some unattained result. To express what is regarded as a fact or a certain result the indicative is used: *Si je vais à Londres, ce sera avec quelqu'un qui sache parler anglais*; *Si je vais à Londres, ce sera avec quelqu'un qui sait parler anglais.* Both these sentences mean: If I go to London it will be with someone who can speak English. In the first of them, the use of the subjunctive indicates that such a person has not yet been secured; in the second, the use of the indicative implies that such a person is actually available.

GAS MANUFACTURE—2

Wood-gas. The process of manufacturing wood-gas is practised only in those countries where wood is plentiful and coal expensive. Riche's gas plant is used, the retorts being of cast iron. The gas consists of hydrogen, carbon monoxide with marsh-gas and ethylene, the carbon monoxide being in larger proportion than in coal-gas, some of it being due to the decomposition of the water which is contained in all wood. Several methods have been proposed for the preparation of peat-gas, which promise great possibilities on account of other products which result. These gases can be carburetted to increase their illuminating powers.

Air-gas. What is known as *air-gas* consists of air carburetted with the vapours of highly volatile hydrocarbons, such as gasoline, carburine, and benzene. The hydrocarbon needs to be very volatile, and of constant and uniform composition. One plant which has been satisfactorily working for some time consists essentially of three parts: (1) A large, shallow cylindrical copper tank, holding 250 gallons, buried some 30 ft. or more from the building, and filled with gasoline through a pipe and closed airtight by a screw tap. Two other pipes, an inlet and outlet, are fitted into the top of the tank, and pass underground to the cellar of the building. (2) In the cellar a pump, worked by a weight on pulleys, forces air through the inlet pipe on to the surface of the gasoline in the tank. Evaporation is rapid—gasoline boiling at from 35° C. to 70° C.—and the mixture of vapour and air is driven through the outlet pipe into (3) an automatic mixer, by which a definite and known quantity of air can be added, so that the proper proportion for burning may be constantly maintained. The apparatus is simple, and requires little attention.

A similar air-gas can be made with ether, but in this case the air is passed through a box containing a fibrous substance which has been saturated with ether.

Hydrogen. Within the last few years the necessity has arisen for the production of large quantities of pure hydrogen cheaply, for use in airships and in the new industry of fat hardening. The chemical method formerly employed, in which dilute sulphuric acid acts upon iron, cannot be used, owing to the enormous quantities of materials which are required. For example, an airship of no exceptional capacity requires from 250,000 cubic ft. to 500,000 cubic ft. of hydrogen to inflate it; and, taking the lower capacity, this means the use of 18 tons of iron and 31 tons of sulphuric acid. The working processes are those of Linde-Frank-Caro and Messerschmitt. The first-named starts with water-gas, separates the carbon monoxide and nitrogen by cold and pressure—these two gases being more readily liquefied than hydrogen—and the carbon dioxide by absorption in caustic soda solution. The Messerschmitt process combines the production of hydrogen by the action of steam on iron, and the reduction of the resulting iron oxide by water-gas, the two reactions taking place at 700° C. and 800° C. respectively.

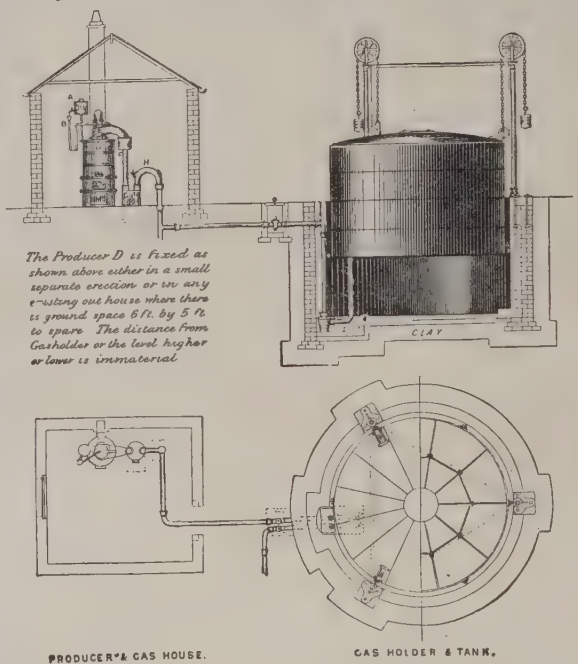
Oil-gas. When oil is subjected to destructive distillation it is broken up—"cracked" is the technical term—and a gas possessing high luminosity and heating power is obtained. The earliest process was invented by John Taylor in 1815, and shortly afterwards a method of compressing the gas was devised so that it could be readily transported—hence the name *portable gas*. It is a convenient method of illuminating railway carriages, buoys, and lightships. The process of "cracking" oil is the basis of new methods of making petrol from paraffin.

Pintsch's Apparatus. The Pintsch system is one in use in many railway companies, the following being a description of the process as used by the Great Northern Railway at Holloway. The plant was designed to make 60,000 cubic ft. of gas per day. The 10 in. D-retorts in which the oil is cracked are made of 1 in. metal, and are 6 ft. in length; they are worked in pairs, and are kept as nearly as possible at a cherry-red heat. Each pair will make from 300 cubic ft. to 400 cubic ft. of gas per hour, and 600,000 cubic ft. to 700,000 cubic ft. of gas before they require renewal. Immediately before the gas enters the hydraulic main, a $\frac{3}{4}$-in. iron pipe, provided with a stop-cock, is tapped in, so that the colour of the gas may be seen, this being the practical test applied to ascertain the quality of the gas, and whether the proper quantity of oil is being admitted. Another test for regulating the supply of oil is to drop a small quantity of the tar from the gas-main upon a sheet of white paper; if too much oil is being admitted to the retort, a greasy ring will be found round the spot of tar; but if the right quantity is being used, no ring will appear.

The furnaces consume 160 lb. to 180 lb. of coke for every 1000 cubic ft. of gas produced. The oil used is a once-refined shale oil; it runs to the retorts from a galvanised iron cistern of 50 gallons capacity through a 1-in. iron pipe, at the end of which is fixed a gun-metal micrometer cock for regulating the supply. From this supply pipe the oil flows into a small funnel attached to a $\frac{3}{4}$-in. siphon pipe, 12 in. deep, connected with the retort; it then falls on a loose tray, preferably of steel, and is instantly converted into a dense brown vapour. The gas issuing from the retorts passes to the hydraulic main, then through air condensers, washers, and purifiers into the meters and gasholders. The purifiers contain a mixture of two parts of slaked lime to one part of sawdust, placed on wicker trays, and are recharged every week. The cylindrical steel storeholders are 17 ft. 6 in. in length, and 4 ft. 3 in. in diameter. They are tested by hydraulic power to 300 lb. per square inch, and are provided with a pressure gauge registering up to 200 lb. per square inch. The gas is forced into the storeholders through a 1-in. extra-strong lead pipe by compressing engines. Each holder is provided with a cock at the bottom for drawing off the condensed hydrocarbon, of which about a gallon is obtained from every 1000 cubic ft. of compressed gas. Each gallon of oil yields 80 cubic ft. to 85 cubic ft. of gas. The oil is run in at about 12 gallons per hour. Other systems are the Keith, Pope, and

Peebles processes. The object aimed at in the last-named—Young, of Peebles—is to produce an oil-gas specially adapted for carburetting water-gas and enriching coal-gas.

Mansfield's Apparatus. A form of oil-gas plant much used for private installations is that made by Mansfield & Sons, Ltd., Liverpool. The illustration [7] shows a sectional elevation of the complete plant, the details of the gas producer being shown in the smaller figure [8]. The producer has a retort suspended in a cast-iron casing, lined with fireclay fittings. The top of the retort is made gas-tight by a lead joint. When the retort is hot enough to make gas, the lead melts, the bonnet sinks into it, thus making an automatic joint. The retort is heated by a coal or wood fire, and a strong red heat as seen through a sight plug is maintained throughout the gas-making process. Oil is stored in a suitable tank in any part of the building. From this tank a pipe is led to the oil syphon of the producer. A small cock attached to the end of the pipe regulates the flow of oil which is permitted to run in a fine stream into the funnel of the oil syphon. Through this it passes into the retort, and is converted into gas. The gas rises into the bonnet, and passes down the standpipe into the hydraulic main, through which it passes into the gasholder. The materials from which oil-gas can be made include creosote, palm-oil, castor-oil, coconut-oil, Rangoon-oil, kerosene, fish-oil, tallow, and unrefined fat.



The Producer D is fixed as shown above either in a small separate erection or in any existing out house where there is ground space 6 ft. by 5 ft. to spare. The distance from Gasholder or the level higher or lower is immaterial

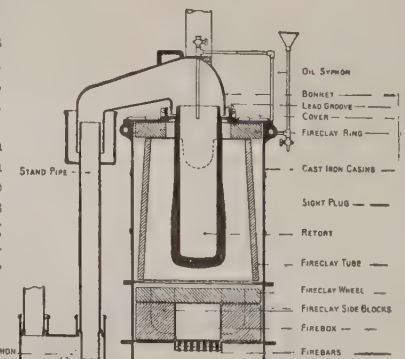
7. MANSFIELD'S OIL-GAS PLANT
(Mansfield & Sons, Ltd, Liverpool)

Water-gas. When water, in the form of steam, is passed through a mass of incandescent coke, the water molecule is decomposed, its constituent elements combining with the coke—a form of carbon—to make carbon monoxide or carbon dioxide and hydrogen. If the temperature of the coke is at about 500° C., carbon dioxide and hydrogen are formed, but at 1,000° C. the products are carbon monoxide and hydrogen. The mixture of gases thus obtained is known as *water-gas*. In discussing the various combustible and non-combustible constituents of gas, it was pointed out that carbon monoxide is combustible, but that carbon dioxide is non-combustible, and thus of no value as an illuminating or heating gas. The object will be, therefore, to produce carbon monoxide in preference to carbon dioxide if the usual properties of a gas are desired. There are, however, cases in which the carbon dioxide is preferable, as will presently be explained. The reaction in making water-gas takes place in two stages—the first, in which the water molecule is decomposed, absorbs heat in course of the change; and the second, when the carbon monoxide is being formed, is a reaction where heat is given out. The process is, on this account, an intermittent one. Air is blown in a blast over glowing coke till the mass becomes intensely hot, the gas being given off at this stage being known as *producer* or *generator gas*. When the coke is hot, steam is blown in in place of the air, water-gas being produced. The reaction rapidly cools the coke, so that it becomes necessary to stop the injection of steam and again blow the coke to incandescence by turning on the air blast. The producer or generator gas is passed into a second vessel filled with firebricks, which it raises to a white heat, and it is into this second vessel or *superheater* that the steam is passed before it goes into the fuel in the generator. Thus water-gas is made for about four minutes, and the heating-up occupies about ten minutes. This question of producer gas will be dealt with later.



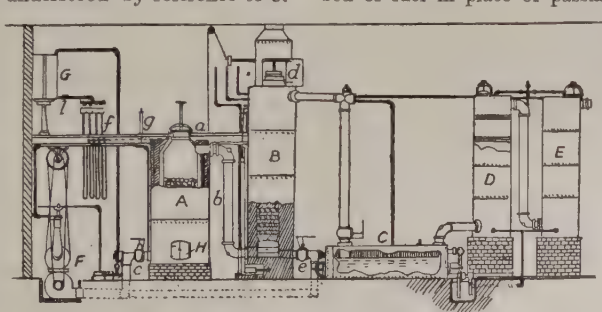
8. DETAILS OF THE GAS PRODUCER

Carburetted Water-gas. It will be remembered that both hydrogen and carbon monoxide give *blue* or non-luminous flames, and to make the gas give a luminous flame it is *carburetted* in a way similar to the enriching process referred to in the article on coal-gas. This carburetting is effected by the hot process in an additional chamber, in which oil is decomposed and the vapours mixed with the water-gas in a manner which will be best understood by reference to our remarks on oil-gas. The enriching may also be carried out in the cold process by allowing the gas to pass into a vessel containing carburine, a mixture of gasoline and benzene, which vessel is surrounded by hot water

to promote evaporation. This, again, will be readily grasped when the section of this article on air-gas is read. Carburetted water-gas is much used in the United States, where gas-coal is comparatively dear, and hence cannot advantageously be used for preparing coal-gas. In this country the large gas companies are in the habit of mixing about 10 per cent. of carburetted water-gas with the coal-gas as a convenient method of raising the candle-power of the latter to the standard candle-power. Water-gas is more poisonous than coal-gas, as it consists mainly of carbon monoxide and hydrogen, the former a very poisonous gas. Moreover, as water-gas is inodorous, it is not so easy to detect leakage. This objection can be got over by giving the gas a strong smell by passing over naphthalene or impregnating with isocyanides or organic sulphides. The objection does not arise in cases where the carburetted water-gas is mixed with coal-gas, but the poisonous properties of carbon monoxide form a reason why the proportion of water-gas should not be unduly increased. If it were not that the public want a gas to give a luminous flame always it could very well be made luminous at the burner by means of an incandescent mantle.

Advantages of Carburetted Water-gas. After referring to the disadvantages of water-gas, it is only just to state the advantages. These are that the gas can be made of high illuminating power; economy in wages, since fewer workers are required than for the manufacture of coal-gas; the small cost of the installation; small area occupied by the plant; the utilisation of coke; freedom of the gas from ammonia and small amount of sulphur compounds to be removed. There is no need to remove the small amount of carbon dioxide, and the apparatus can be got ready for working in less than four hours, which is a convenience in case of a suddenly increased demand for gas. In coal-gas works it is economical to use the red-hot coke as it is drawn from the retorts.

Lowe's Water-gas Process. Having stated the chief points in the manufacture of water-gas, a few details of some of the processes actually employed may be given. In the Tessié du Motay process the water-gas is made from anthracite (in place of coke) and steam, then purified by passing through a lime-box, and finally carburetted by the cold process, the resulting mixture of water-gas and naphtha, or carburine vapour, being led through specially arranged retorts to ensure decomposition of the hydrocarbon, and finally stored. Lowe's process will be best understood by reference to **9**. In this the decomposition of the naphtha is carried out simultaneously with the production of the water-gas—that is, it is carburetted by the hot process. A is the generator, filled with anthracite through the manhole *a*. A fan, F, sends a current of air into the generator through the valve *c*; the gases escaping through the pipe *b* into the superheater B, filled with stacked firebricks; when the gases contain enough carbon monoxide to burn, air is also blown in at the base of the superheater



9. LOWE'S WATER-GAS PLANT

through the valve *e*, the products of combustion escaping into the open at the top through *d*. When the requisite temperature is attained, *c*, *d*, and *e* are closed, and the fan nearly stopped, a very gentle current being still maintained through small orifices in *c* and *e*, purposely arranged to prevent back-rush of water-gas into the air main, which otherwise might cause an explosion. Steam is then turned on at the base of the generator, and a stream of naphtha at the top supplied from the tank by means of a series of distributing tubes. The mixture of hydrogen, carbon monoxide, and a little carbon dioxide formed in the generator, vaporises the naphtha, and the mixed gases act on one another in the superheater, ultimately producing an illuminating gas of high quality, when the steam and naphtha supplies are properly proportioned. The gas is washed in the purifier C, and the two towers, D and E, and stored. The steaming operation is continued for twenty minutes, when the steam is shut off, more anthracite filled in through the manhole, and the cycle of operations begun again. Every few hours (six to twelve) the doors, H, at the base of the generator are opened and the anthracite residue raked out. As will be seen, the product is a mixture of oil and water-gases. All sorts of variations of this process are in use. In one the superheater is filled with lumps of lime to free the gas from carbon dioxide. The Granger plant is arranged so that the naphtha is forced in under pressure, thus facilitating its gasification, and in the Hanlon and Leadley process bituminous coal is used in place of anthracite. Humphrey's apparatus consists of two generators, two carburettors, and two superheaters. The generators are connected by means of a flue, and each of them is also in connection with a carburettor and a superheater, the object being to enable the process to be alternately worked from the left and right.

The Dellwik-Fleischer System. In the water-gas processes just described, the fuel is raised to incandescence by blowing air through so deep a bed of fuel that the chief products are carbon monoxide and nitrogen (from the air). One pound of carbon develops only 2,400 heat-units when burnt to carbon monoxide, but 8,080 when burnt to carbon dioxide, for the reason explained in the opening remarks about the water-gas reaction. Carl Dellwik has devised a process by which the products of the "blow" are carbon dioxide and nitrogen, and thus the additional heat-units are made available in raising the temperature of the bed of fuel in place of passing into the producer gas. The result is that twice as much water-gas is obtained, the extra heat reduces the "blow" period, and allows the "run" (steam admission period) to be prolonged. The flow of steam to the fuel is regulated so that even at the end of the run there is no excess of steam to oxidise the carbon monoxide to dioxide. A ton of good coke yields 70,000 cubic ft. of water-gas in place of 34,400 by the older process. Under the older processes the cost of 1,000 cubic ft. of water-gas is from 4d.

to 6d.; by a large Dellwik-Fleischer installation the cost is below 3d. The gas produced by the Dellwik process has been successfully utilised at Cleethorpes for mixing with coal-gas by passing it into the retorts during carbonisation. Dr. Fleischer improved the original Dellwik process, hence his name becomes to be associated.

Methane Hydrogen Gas. This is the name of a process which has been successfully adopted at Sligo and Truro. The generator is filled with coke, and then blown up to incandescence, the waste gas escaping part of the way up the generator to the stack pipe, so that the fuel above is dried and heated before it comes down into the hot zone, and also serves to filter out the finely divided carbon produced during the "run." When the requisite temperature has been attained the valves are altered, and steam and tar are injected into the body of incandescent fuel. The tar is decomposed into carbon and gaseous products—containing methane—the steam combining with the coke and separated carbon to produce water-gas. A further quantity of steam injected at the bottom of the generator serves to produce ordinary water-gas, which passes away and mixes with the other gases. This gas is mixed with ordinary coal-gas in the foul main, where it takes up a considerable quantity of illuminants from the hot tar. Methane hydrogen is claimed to take up benzene better than ordinary water-gas in the carburetting process. Such a carburetted methane-hydrogen gas costs 8·92d. per 1,000 cubic ft. at Truro.

Producer-gas. This term is applied to the gas obtained in the producer or generator of the water-gas apparatus. It will be remembered that air was passed into the generator filled with coke, a gas was produced which was used to heat the second chamber, into which steam was driven and decomposed into water-gas. This may be taken as an instance of the utilisation of producer-gas; but it finds many employments in metallurgical operations, boiler firing, gas-engines, and in glass and pottery manufacture. It is also known as *Siemens' gas*, because producer-gas was economically made in a regenerative furnace of the Siemens' type. The producer-gas is made in numerous different furnaces. In some the gas is enriched by being used for distilling coal; and, again, if steam and air are injected, a mixture of producer-gas and water-gas is obtained—the so-called *semi-water-gas* or *Dowson gas*. The amount of steam that can be used is limited—from the reasons which we have dealt with in the paragraph on water-gas—and is arranged so that the heat generated by the air equals the heat absorbed by the steam. Producer-gas contains a large proportion of nitrogen from the air that is injected, and as nitrogen is a non-combustible gas, producer-gas is comparatively poor in heating properties; its flame also is non-luminous. The French call the gas *gaz pauvre*, or *poor gas*. Although the gas is poor, it can be produced in large quantities, and very cheaply. On this account producer-gas can be used freely, and still be an economical source of power. Carbon dioxide is also found in producer-gas, but the object is to make carbon monoxide in preference, as only the latter is combustible. Some average analyses will be given later in comparing the composition of several gases. In many producers anthracite is used in place of coal, as the tar produced with bituminous coal entails purification plant, the gas having a clogging action when used in gas-engines if it contains tar.

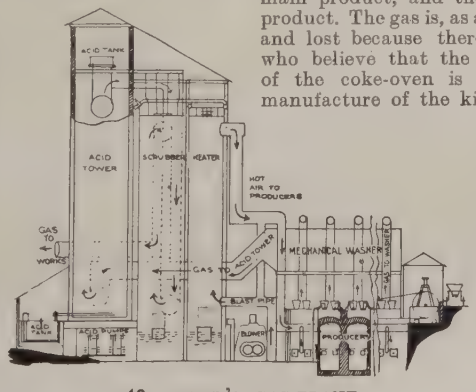
Types of Producers. The Bischof producer of 1839 is the basis of most types that have since been invented. The Siemens' gas producer was brought out in 1861. These early types of producers had open ashpits, with draught produced as in ordinary furnaces, and much heat was lost. Succeeding types are provided with closed hearths, and are produced with numberless variations in the arrangement of the parts. Prof. A. H. Sexton divides closed producers into the following five groups: (1) bar bottom; (2) solid bottom; (3) water bottom; (4) automatic; (5) blast furnace. The Dowson producer, one of the best known of the bar bottom type, was patented in 1878 (No. 3997) and 1881 (No. 2859). The air and steam were admitted through the bars. The clinker from the fuel accumulates on the bars of the furnace, and needs stoking to remove it. The Wilson producer of 1876 (No. 3949) is an example of the solid-bottom producer. The fuel rests on the solid bottom of the generator upon a layer of clinker. The clinker is drawn off near the bottom, and air blown in just above the layer of clinker, which is always left in the producer. The clinkers are removed every twenty-four hours through narrow side doors, bars being put across to support the fuel during the operation. Solid-bottom producers are thus intermittent, but this is got over by arranging a water-seal as in the water-bottom producers. The ashes fall into water, and no gas escapes. The heat of the ashes vaporises some of the water, which passes into the producer. The Duff producer (patent 15646, of 1901), the Smith and Wincott producer (patent 12895, of 1901), and the Wilson water-bottom producer are representative examples of this type. In the automatic producers the ashes are continuously removed by mechanical means. The Wilson automatic producer does this by a constantly revolving screw, which slowly pushes out the ashes. Space will not permit of details being given of the numerous producers that have been patented, and which fall under one or other of the above types. The chief improvements consist in means of removing the tar from the gas; heating the air and steam before use; special methods of charging; special arrangements for supplying the air and steam; varieties in grates; producers raising own steam; arrangements for breaking up clinker or fuel; supplying the air and steam at the top and drawing off the gas lower down; feeding at the bottom.

Suction Gas-producers. The constantly increasing use of gas-engines has ensured the evolution of the gas producers along economic lines. The types hitherto dealt with have needed air and steam forcing into the producer, with the consequence that the gas was under slight pressure, from which fact the type has been distinguished as *pressure gas-producers*. From these a new type requiring neither steam-jet nor air-blower has been evolved, the air being drawn into the producer by a suction pump attached to the gas-engine, being known as *suction gas-producers*. With the older type of pressure producers a boiler was needed to generate steam, and a gasholder in which to store the gas for use; while with the suction type the gas is taken direct to the combustion chamber of the engine. The boiler is supplanted by an *evaporator* or *vaporiser*, which in small plants is built frequently on the top of the producer in the form of a water jacket, and in large plants close to the producer in the form of a tubular evaporator. This evaporator is generating the steam required by utilising the waste heat of the producer and of the gas, which is of considerable advantage, as

compared with the old system, the firing of a separate boiler being dispensed with. The advantage of a suction gas-producer are automatic generation of the gas by the engine; highest and best utilisation of fuel; no boiler or gasholder required; can be erected without danger in any convenient place; easy to start and to run; no soot, smoke or odour; no explosion possible; and small floor space required. The origin of the type is the Benier producer, which was patented 1894, and has been specially developed on the Continent. A complete suction gas-producer plant consists of a blower which, up to 150-h.p., is driven by hand; a producer, an evaporator, an overflow water-pot, a scrubber, and a small equalising tank or *expansion box*. In plants above 75-h.p. a sawdust scrubber is advantageously inserted behind the wet scrubber, and in plants where two or more engines are fed from the same producer a small gasholder with automatic regulation is used.

The producer consists of an iron shell lined with firebrick and provided with a suitable hopper. The grate area, according to the quality of fuel, is 0·8 to 1 sq. ft. for every 10 horse-power. The scrubber consists also of a sheet-iron shell, and is filled preferably with broken coke. Before starting the engine the fuel in the producer is heated up by means of a blower until the gas is burning well at the test-cock. When this point is reached the blower is stopped, and the engine started in the usual way. The engine then draws by its own sucking action the necessary amount of air and steam through the fuel, and is producing its own power-gas. From the producer the gas is drawn through the scrubber and the equalising tank to the engine. The gas-making process continues so long as the engine is moving, and stops when the engine stops. Anthracite, charcoal, or coke can be used in suction gas-producers.

Mond Gas. Dr. Ludwig Mond, in studying the question of obtaining a cheap fuel gas, has evolved a method in which slack coal is used, and the ammonia produced by the combustion is recovered. The gas is really a producer-gas, but is, on account of the novel method of production, generally distinguished as Mond gas. The gas is being produced on an enormous scale, and is distributed by means of pipes in a large district in Lancashire. The following is a brief description of the plant used, which will be made clearer by referring to the illustration [10]. The producer is provided with a water-seal, and is constructed so as to allow the ash, which is the only residue, to descend into the water, from which it is easily removed without interfering in any way with the working of the producer. The process of combustion is carried out at a comparatively low temperature, with the twofold object of preventing the formation of clinkers in the producer and of providing against the destruction of ammonia. This is accomplished by introducing into the producer a blast of hot air and steam. The quantity of steam required when it is desired to recover the ammonia from the gas is equal to 2½ tons per ton of fuel gasified, but of this about 1 ton is automatically recovered and used over and over again. After leaving the producer the gas is passed through a regenerator arranged so that part of the heat or gas and steam entering it is transferred to the blast of air and steam on its way from the air-heating tower to the producer, the gas being consequently cooled to a corresponding temperature. The gas then passes to a mechanical washer, which further reduces the temperature and removes all soot and dust. The next step is the recovery of the ammonia, and the gas is for this purpose passed through an acid tower, where the ammonia is completely absorbed by a dilute solution of sulphuric acid. The solution circulates through the acid tower again and again until it contains from 36 per cent. to 38 per cent. of sulphate of ammonia. Continuity of the process is provided by adding from time to time fresh supplies of sulphuric acid and withdrawing corresponding quantities of sulphate liquor. The latter is evaporated, yielding at once a solid sulphate of ammonia of good saleable quality. After the gas has been washed of its ammonia products, it passes through a final cooling and cleaning water-tower, and is then ready for use. As the gas is cooled in this final tower the steam with which it was saturated is condensed, and the cleaning water which enters the tower cold is delivered hot; and this, after passing through tar-separators, is again pumped to the air-heating tower to heat the air required for the producer blast. The final cost of 140,000 cubic ft. to 160,000 cubic ft. of gas from a ton of fuel is put at 4s. 11d. About 90 lb. of sulphate of ammonia is obtained from each ton of coal.



10. MOND'S GAS-PLANT

Coke-oven Gas. In the manufacture of coal gas, as we have seen, the gas is the main product, and the coke, although used for several other purposes, is the by-product. The iron smelter requires a coke that is compact, heavy and even, and to produce such a coke special furnaces are used, known as *coke-ovens*. Here the coke is the main product, and the gas given off is the by-product. The gas is, as a rule, completely neglected and lost because there are many iron makers who believe that the recovery of the products of the coke-oven is not consistent with the manufacture of the kind of coke which is most suitable for the blast furnace. As some 13,000,000 tons of coal is coked in the United Kingdom in beehive ovens for the manufacture of pig iron, it will be apparent that the loss is tremendous. Many recovery or by-product coke-ovens have been invented, the principle being that the gas is drawn away from the ovens and means employed to remove the tar and ammonia. The gas is used for heating the coke-ovens, in gas-engines, and is now being adapted for illuminating purposes. In large installations of by-product coke ovens two kinds of gas are separately collected; the richer gas coming off during the first part of the process can be used as an illuminant, the second portion of the coking yielding fuel gas. The other by-products, tar and ammonia, are recovered by similar methods to those used in purifying coal gas, and already described.

Blast-furnace Gas. The blast furnace used for smelting iron ore generates a large quantity of inflammable gas known as *waste gas.* The last name expresses the universal practice of iron makers up to a few years back, when efforts were directed to utilising this wasted form of fuel. The gas, owing to the velocity with which it passes from the furnace, is laden with dust; but this is neglected when the gas is employed for heating the blast, or as fuel under boilers. When required for use in gas-engines, the gas must be cleaned, or it soon blocks up the valves of the explosion chamber. Properly cleaned furnace gas is an ideal gas for gas-engines, as, when mixed with air and compressed, it is found to be a slow but very reliable explosive. A portion of the gas is used for driving the gas-engine which produces the blast, but much surplus gas remains for other economic purposes.

Composition of Gas. The following typical analyses of illuminating and fuel gas are interesting as showing the relative composition. The figures (percentages) were given by Mr. Willard L. Case in a communication to the New York section of the Society of Chemical Industry in 1905:

COMPOSITION OF ILLUMINATING AND FUEL GASES.

—	Natural gas.	Coal-gas.	Oil-gas.	Water-gas.	Carburetted water-gas.	Producer-gas from			Coke-oven gas.	Blast-furnace gas.
						Anthracite.	Bituminous coal.	Coke.		
Hydrogen	3·0	46·0	32·0	48·0	40·0	20·0	10·0	10·0	50·0	1·0
Methane	92·0	40·0	48·0	2·0	25·0	—	3·0	—	36·6	—
Ethylene	3·0	5·0	16·5	—	8·5	—	0·5	—	4·0	—
Carbon monoxide ..	—	6·0	—	38·0	19·0	25·0	23·0	29·0	6·0	27·5
Carbon dioxide ..	—	0·5	—	6·0	3·0	5·0	5·0	4·5	1·5	11·5
Nitrogen	2·0	2·0	3·0	5·5	4·0	49·5	58·0	56·0	2·0	60 0
Oxygen	—	0·5	0·5	0·5	0·5	0·5	0·5	0·5	0·5	—

Acetylene. At the beginning of the consideration of illuminating gas, acetylene was mentioned as both a combustible and luminous gas present in small quantities in coal-gas. Acetylene has, within recent years, been prepared for use by itself as an illuminant, this having been rendered possible by the discovery of a cheap method of producing it.

Action of Water on Carbides. When water is brought into contact with calcium carbide, acetylene is produced in accordance with the following chemical reaction:

$$CaC_2 + 2H_2O = Ca(OH)_2 + C_2H_2$$

calcium carbide + water = calcium hydrate + acetylene. The production of the gas is so easily and simply effected that it is no wonder that the use of acetylene soon became popular in places where coal-gas or carburetted water-gas were unattainable. Besides calcium carbide there are other carbides prepared in the electric furnace, but none of them have assumed the importance of calcium carbide. Lithium carbide, barium carbide, strontium carbide, potassium carbide, and sodium carbide, all give off acetylene when brought into contact with water, but aluminium carbide gives off methane and manganese carbide, a mixture of methane and hydrogen. [See page 3668.]

Calcium carbide treated with oil or fat is not so liable to deterioration by damp, but is still capable of slowly evolving acetylene when it is immersed in water.

Storage. On account of the action of water on calcium carbide it is necessary that it be stored from moisture—large quantities in strong iron drums, and small quantities in hermetically sealed tins. This property also accounts for the fact that the storage of calcium carbide is regulated by the Petroleum Act, except when quantities of 28 lb. in 1 lb. packages are stored.

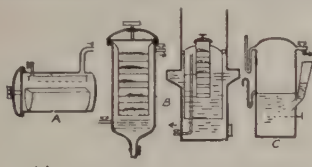
Properties of Acetylene. The light yielded by acetylene more nearly approaches sunlight in light rays, but it has more blue or violet rays (chemical rays). The illuminating power of acetylene as compared with coal-gas varies with the type of burner employed. In a suitable burner, 5 cubic ft. of acetylene per hour will give 240-candle power, while the same quantity of coal-gas gives 16-candle power. Acetylene is, however, generally burnt in small burners using from ½ cubic ft. to 1 cubic ft. per hour, when the illuminating power is from six to ten times as great as that of coal-gas. There is less heat developed by combustion of acetylene for given yield of light than most other illuminants. The distinctive smell of commercial acetylene makes it easy to detect leaks. The limits of explosibility of acetylene mixed with air are 3·1 per cent. to 24·1 per cent., which is a slightly wider range than other combustible gases of commerce. The effects of an explosion would probably be no greater than with ordinary gas. Compressed acetylene is dangerous, and its manufacture, importation, or storage at greater pressure than 100 in. of water is illegal in the United Kingdom. Acetylene is, however, allowed to be compressed along with oil-gas; and the exemption extends also to acetylene compressed into porous material, both with or without acetone. The last-named liquid has a remarkable power of absorbing acetylene, the liquid being known as *dissolved acetylene.* A cheaper solvent is acetaldehyde. Other uses are for autogenous welding, and in self-starting devices for motors.

Impurities in Acetylene. It is the impurities in acetylene which give the gas its unpleasant smell, hence every care needs to be exercised to use only pure ingredients in making calcium carbide. Phosphorus compounds in the lime used become calcium phosphide, which, when moistened with water, yields phosphine; this gives not only an unpleasant odour but also a white haze of ammonium phosphate in the air when burnt in a closed room. The highest proportion of phosphine ever met with has been 2·3 per cent. Sulphur compounds are seldom present, but sulphuretted hydrogen may be detected in cases where the gas has been improperly generated or where aluminium sulphide is present in the carbide. Crude acetylene always contains ammonia, which arises from the aluminium or calcium nitrite in the carbide. It is an objectionable impurity, as it corrodes the brass fittings, and, producing pyrol at the burners, stops them up. Traces of hydrogen silicide, oxygen, nitrogen (or air), hydrogen, carbon monoxide, and

methane, have also been found in varying small amounts.

Purification of Acetylene. The substances which have been proposed as chemical purifiers for acetylene are (1) ordinary ferric hydroxide, as used for coal-gas; (2) heratol, a solution of chromic acid in acetic or sulphuric acid absorbed in kieselguhr; (3) acagine, a mixture of bleaching powder, with 15 per cent. of lead chromate; (4) puratylene, a mixture of bleaching powder with calcium chloride and calcium hydroxide; and (5) frankoline, a solution of copper and iron chloride absorbed by kieselguhr. These materials have been subjected to an examination and tested for efficiency by Keppeler, and were, as a result, placed in the following order: Ferric acid is practically useless, but one kilo of the other four materials purifies the following quantities (in litres) of acetylene; heratol, 5,000; frankoline, 9,000; puratylene, 10,000; acagine, 13,000. In practice, these numbers may be increased from 10 per cent. to 20 per cent.

Types of Generators. There have been up to the present time some hundreds of different apparatus [11] constructed for the purpose of generating acetylene from calcium carbide. These have been classified by Professor V. B. Lewes into the following three classes, into one or other of which all the generators at present on the market fall.



11. TYPES OF ACETYLENE GENERATORS

1. Those in which water is by various devices allowed to drip or flow in a thin stream on to a mass of carbide, the evolution of the gas being regulated by the stopping of the water-feed.

2. Those in which water in volume is allowed to rise in contact with the carbide, the evolution of the gas being regulated by the water being driven back from the carbide by the increase of pressure in the generating chamber.

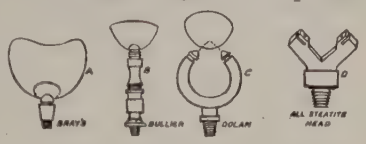
3. Those in which the carbide is dropped or plunged into an excess of water.

These types are again subdivided into (*a*) *automatic* and (*b*) *non-automatic*.

By automatic generators are meant those which have a storage capacity for gas less than the total volume which the charge of carbide is capable of generating, and which depend upon some special contrivance for stopping contact between the water and carbide. Non-automatic generators are those in which a holder of sufficient capacity is provided to receive the whole of the gas made from the largest charge of carbide which the apparatus is capable of taking.

Choosing a Generator. The factors to consider in choosing a generator are those which guided the Departmental Committee appointed to advise the Explosives Inspectors in 1900. The Committee consider that in selecting an acetylene generator regard should be had to the following desiderata: (1) simplicity of action and design; (2) strength of construction; (3) high efficiency, as indicated by the yield of gas per lb. of carbide; (4) low pressure in generator; and (5) facility of removal of the residue.

Acetylene Burners. One of the chief difficulties in the burning of acetylene is the quantity of smoke which is produced, which causes endless trouble by growths of carbon which form at the tips of the burners. Burners using 0·75 cubic ft. to 1 cubic ft. of acetylene per hour are the largest that can be used without unpleasant effects. The acetylene is mixed with air at the burner in the most successful type, an air intake being arranged at the tip of the burner. The Naphey is a popular kind. In this, two small jets of acetylene meet to form a flat flame, with very little tendency to produce smoke or become choked. Other types are shown in 12.



12. TYPES OF ACETYLENE BURNERS

Installation Hints. As there are many points of difference between the fittings used for coal-gas and acetylene, the requirements are briefly indicated separately. The generator and holder should be in a well-ventilated place outside the house, the place being capable of being warmed with hot-water pipes in case of severe weather. The holder should be of such a size as to contain sufficient gas to last the whole evening or the longest period the burners will be alight. As regards the size of the pipes used for supplying acetylene, it must be remembered that a given size pipe will supply three times as many burners with acetylene as with coal-gas. For fifteen burners ½ in. pipe is used; for sixty burners, ¾ in. Iron barrel piping should be used, and joints screwed together without paint or packing. Taps require to be of best quality brass, as cheap fittings are soon corroded. In starting an installation, care must be taken that all the air is out of the pipes. It is best to take samples of gas from each burner in a test tube, and test with a match before applying a light to the burner for the first time. The pressure at which the gas is supplied should not be more than 2½ in.

Yield and Cost of Acetylene. One pound of calcium carbide will yield 5 cubic ft. of acetylene; in practice it is usual to reckon the quantity as 4 cubic ft. Acetylene is reckoned to cost £2 per 1,000 cubic ft. in the holder, and if it is distributed on a commercial scale, the cost of distribution will double this. Coal-gas costs 1s. 2d. per 1,000 cubic ft. in the holder, this being doubled by the expense of distribution and profit. It will thus be seen that acetylene cannot displace coal-gas where the latter is obtainable.

Acetylene Lamps. Many kinds of portable acetylene lamps have been devised, but the great difficulty in the case of table lamps has been to ensure freedom from smell. It will be obvious that similar conditions and principles apply in constructing table lamps as are indicated in the case of generators. It is usual to arrange a filter of silicate wool before the acetylene is passed into the burner, so as to guard against mechanical impurities being taken into the flame. Acetylene cycle lamps are much in use on account of the brilliant illumination obtained. Such lamps are more expensive to maintain than oil lamps, and the greater light obtained is not always a recommendation. Acetylene motor lamps are a development of the cycle lamps.

Gas Meters. To measure the quantity of gas used by a consumer, gas is passed through a meter which mechanically records the volume of the gas. The meter is fixed within 2 ft. 6 in. of the main cock. The gas is measured in cubic

feet, for which, curiously enough, no standard existed till the passing of the Sale of Gas Act 1859. This Act fixed the standard cubic foot as the space occupied by 62·321 lb. avoirdupois of distilled water, weighed in air at 62° F., and at normal atmospheric pressure. Meters are tested for accuracy by passing through them a measured volume of gas from a small gasholder. The following are the capacities of a few ordinary size meters :

Size.	Size of inlet and outlet pipe.	Measuring capacity per revolution.	Per hour.
	in.	c. ft.	c. ft.
10 light	1	$\frac{1}{4}$	60
20 ,, ...	$1\frac{1}{4}$	1	120
30 ,, ...	$1\frac{1}{4}$	$1\frac{1}{2}$	180
51 ,, ...	$1\frac{1}{2}$	$2\frac{1}{2}$	300
100 ,, ...	2	5	600
250 ,, ...	4	$12\frac{1}{2}$	1,500
1,000 ,, ...	7	50	6,000

Wet Meters. There are two types of meters in use, the wet meter and the dry meter. The former is constructed on the model of the station meter, and consists of three essential parts : (1) a hollow drum or wheel rotating in water ; through this drum the gas passes, and as the drum rotates it actuates the dial index, recording automatically the gas passed ; (2) a compensating arrangement for keeping the chamber in which the drum revolves at a constant level ; and (3) the index, which shows the amount of gas passed. The measuring wheel is of inflexible material, but the water in the meter is liable to freeze in cold weather. For this reason the meter requires to be protected from changes of temperature, and as an additional precaution, glycerine is added to the water to lower the freezing-point. Salt, magnesium chloride and calcium chloride are sometimes used in place of glycerine, but corrosion of the interior of the meter often results.

Dry Meters. This type of meter works on the principle of an ordinary bellows. Gas enters and leaves compartments having flexible leather sides, alternately through valves which open and shut at the proper moment. One of the best-known makers of dry meters thus describes his make of dry meter :

It consists of a cylinder divided by a plate in the centre, into two separate cylindrical compartments, which are closed at the opposite ends by metal discs ; these metal discs serve the purpose of pistons, and they are kept in their places by a kind of universal joint adapted to each ; the space through which the discs move, and, consequently, the means of measurement, is governed by metal arms and rods, which space, when once adjusted, cannot vary. To avoid the friction attending a piston working in a cylinder, a band of leather is attached, which acts as a hinge, and folds with the motion of the disc ; this band is not instrumental in the measuring, so that, if it were to expand or contract, the registering of the meter would not be affected, inasmuch as it would only decrease or increase the capacity of the hinge, the disc being still at liberty to move through the required space ; the leather is also distributed in such a manner, being curved, and bending only in one direction, that it prevents any creases or wrinkles forming, and renders it therefore much more durable. The arrangement of the valves and arms are somewhat different to that of the steam engine, although somewhat similar in principle.

Most dry meters are composed of two chambers ; but there may be three or more, without difference of principle. The chambers fill and discharge alternately or in succession, and the action of the valves is accurately registered in the mechanism that regulates the dials of the index. A common error is the supposition that the leather enclosing the space between the discs actuates the gas ; but the whole of the work is performed by the latter, which are really pistons receding to let the gas fill the chamber and advancing to drive it out. Though delicately adjusted, the mechanical action is really very simple.

How to Read the Meter. There is no mystery about the dial of a gas meter. It is perhaps because some people have never considered the subject that they think it difficult to read a gas meter. It is as simple as telling the time by a clock. There are three or more dials in the little compartment at the top of the meter. One of these indicates, perhaps, 2 cubic ft., an arrow usually being placed to indicate the direction of the hands. When a large quantity of gas is being burnt the little hand in the unit dial is kept busy, and the consumer can get a good idea of the cost per hour of, say, a cooking stove. The other dials register hundreds, thousands, ten thousands, and million cubic feet, the hands moving on the dial just as on the smaller dial, but naturally much slower. At a given date—say, the beginning of a month—the quantity is noted, and at the end of the month the index is again read off, the difference between the two amounts being the quantity consumed during the month. In the case of illuminating devices used at public rejoicings, the gas is generally taken direct from the main and a charge made of so much per jet per hour, with a minimum charge of 50s.

Prepayment Meters. These meters, which are actuated by a coin, are also known as slot meters. They were invented in 1887, and are of various kinds—Brownhill's, Price's, Cutler's, Braddock's, Cowan's, Glover's, and Parkinson's—adapted for taking either pennies, sixpences, shillings, florins or half-crowns. The slot meter is extremely popular with people of moderate means, who can thus use a cheap illuminant without running into debt.

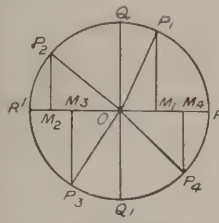
Slot-meter Mechanism. At the front of the meter is the slot. Within is a delicate balancing arrangement which works on the valve of the meter. This balance is connected with the index, and as soon as the drum cylinder has revolved the allotted number of times, the balance is disturbed, and the coin drops down, and the supply ceases. As meters are made to give out quantities of gas for a sixpence, a shilling, a florin, or half a crown, it is easy to see that the weight of the coin, except as a means of starting the action, has nothing to do with measuring the gas.

Gas-fitting. From the meter, pipes convey the gas to the various parts of the house. The supply pipes are best of wrought iron, but composition pipes are much used. The latter are more liable to damage, and many cases of leakage have been caused by nails having been driven into the softer piping. The liability to compression and consequent constriction in the supply of gas is another fault often found with composition pipes. Cheap piping is to be avoided, as soundness is a very necessary quality in gaspipes. All lines of piping should be laid with a gradient, so that condensed moisture can drip or drain back into the risers. Drip pipes should be provided where necessary. Piping should be exposed as much as possible to facilitate future examination, and where the pipes are laid beneath floors, the boards should be screwed and not nailed down. In searching for leaks in pipes, a light should not be used, but the suspected parts painted with a strong soap solution; bubbles will show themselves if the least trace of gas is escaping. The work of the gasfitter has been described on page 5369.

Definition of the Ratios. Relations Between Ratios of the Same Angle. Changes in Magnitude of the Ratios.

TRIGONOMETRICAL RATIOS

8. The Trigonometrical Ratios. Suppose an angle of any magnitude A [see note, Art. 4] to be traced by the revolution of OP from the initial position OR. Draw QOQ′ at right angles to ROR′. Unless the angle A is an exact number of right angles, the revolving line must take up some position in one of the four *quadrants* ROQ, QOR′, R′OQ′, Q′OR. In the figure, four different values of A are shown, corresponding to the four positions P_1, P_2, P_3, P_4 of P.



Draw PM ⊥ to OR. Then OM is the projection of OP on the initial line, and MP is equal to the projection of OP on OQ (which makes + 90° with the initial line). From the three quantities, OP and its projections, we can form *six* ratios. These ratios are of great importance in treating of the angle A, and each has a separate name.

(1) The ratio of MP to OP is called the *sine* of the angle A.

(2) The ratio of OM to OP is called the *cosine* of the angle A.

(3) The ratio of MP to OM is called the *tangent* of the angle A.

The remaining three ratios are formed by inverting the first three. Thus,

(4) The ratio of OP to MP is called the *cosecant* of the angle A.

(5) The ratio of OP to OM is called the *secant* of the angle A.

(6) The ratio of OM to MP is called the *cotangent* of the angle A.

The *order of the letters* in the above ratios must be carefully noted, since OM and MP stand for the projections of OP on OR and OQ respectively, and *these projections vary in sign according to the quadrant in which* OP *lies.* For example, if A is an angle lying between + 5 right angles and + 6 right angles, the revolving line will be in the second quadrant, such as OP_2, and its projection OM_2 is then *negative* [Art. 7]. The cosine of the angle A is then $\frac{OM}{OP}$, *i.e.*, a *negative* quantity, by the algebraic rule of signs.

The six ratios thus defined are called the trigonometrical ratios of the angle A. They depend only on the magnitude of A, and not on the length of OP. For if OP were taken of a different length, the new triangle, OPM, would be similar to the old one, and therefore (*Prop.* 56) the ratios of the sides would be the same as before.

9. Instead of "sine of the angle A," etc, we speak of sine A, cosine A, and so on; while, in writing them, we abbreviate them into sin A, cos A, tan A, cosec A, sec A, and cot A respectively.

10. From the above we see that to obtain the ratios of any given angle we take any point in either of the arms containing the angle, and draw a perpendicular from that point to the other arm, produced if necessary. The beginner will do well always to try and imagine that the arm to which he draws the perpendicular is in the position OR of the figure to Art. **8**; he will then have no difficulty in seeing in which quadrant the other arm must lie, and, consequently, whether OM and MP are positive or negative.

11. Note that the ratios of an angle are mere *numbers*, or *fractions.* We may therefore have any *power* of a ratio. For example, the third power of sin A would be $(\sin A)^3$. This is always, for convenience, written $\sin^3 A$. Again, such an expression as cos A . tan B means the *product* of the cosine of angle A and the tangent of angle B.

12. Relations between the Ratios of the same Angle. From the definitions of Art. **8** it is evident that

$$(1)\quad \sin A = \frac{1}{\operatorname{cosec} A}.$$

Similarly,

$$(2)\quad \cos A = \frac{1}{\sec A},$$

and

$$(3)\quad \tan A = \frac{1}{\cot A}.$$

Also,

$$(4)\quad \tan A = \frac{MP}{OM} = \frac{\frac{MP}{OP}}{\frac{OM}{OP}} = \frac{\sin A}{\cos A};$$

and, therefore,

$$\cot A = \frac{\cos A}{\sin A}.$$

By referring to the figure of Art. **8** we have, from *Prop.* 34,

$$OM^2 + MP^2 = OP^2.$$

Hence,
$$\frac{OM^2}{OP^2} + \frac{MP^2}{OP^2} = 1;$$

or,
$$\cos^2 A + \sin^2 A = 1.$$

Dividing both sides of this equation by $\cos^2 A$, and using (2) and (4) we get

$$1 + \tan^2 A = \sec^2 A.$$

Similarly, dividing by $\sin^2 A$, we get

$$\cot^2 A + 1 = \operatorname{cosec}^2 A.$$

13. The five results just proved must be committed to memory—namely,

(1) $\sin A = \dfrac{1}{\operatorname{cosec} A}$.

(2) $\cos A = \dfrac{1}{\sec A}$.

(3) $\tan A = \dfrac{1}{\cot A}$.

(4) $\tan A = \dfrac{\sin A}{\cos A}$

$\cot A = \dfrac{\cos A}{\sin A}$.

(5) $\sin^2 A + \cos^2 A = 1$

$1 + \tan^2 A = \sec^2 A$

$1 + \cot^2 A = \operatorname{cosec}^2 A$.

It is generally convenient, in proving an identity, to express the other ratios in terms of the sine and cosine, by means of these relations.

EXAMPLE. Prove that

$$\frac{\cot A + \tan B}{\tan A + \cot B} = \cot A \,.\, \tan B.$$

The expression on the left

$$= \frac{\dfrac{\cos A}{\sin A} + \dfrac{\sin B}{\cos B}}{\dfrac{\sin A}{\cos A} + \dfrac{\cos B}{\sin B}} = \frac{\dfrac{\cos A \cos B + \sin A \sin B}{\sin A \cos B}}{\dfrac{\sin A \sin B + \cos A \cos B}{\cos A \sin B}}$$

$$= \frac{\cos A \sin B}{\sin A \cos B} = \frac{\cos A}{\sin A} \times \frac{\sin B}{\cos B} = \cot A \,.\, \tan B.$$

The working of such examples should cause no difficulty if the five formulæ are well known, and if it is remembered that sin A, etc., are *numbers—i.e.*, that the example is simple *arithmetic*.

14. The five relations between the six trigonometrical ratios proved in Art. **12** enable us to express any five of the ratios in terms of the sixth.

EXAMPLE. Express the other trigonometrical ratios in terms of the tangent.

From (5) we have

$$\sec A = \sqrt{1 + \tan^2 A};$$

$$\therefore \cos A = \frac{1}{\sqrt{1 + \tan^2 A}}.$$

Hence,

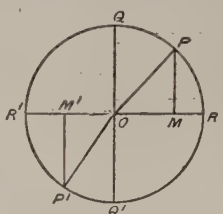
$$\sin A = \sqrt{1 - \cos^2 A} = \sqrt{1 - \frac{1}{1 + \tan^2 A}} = \frac{\tan A}{\sqrt{1 + \tan^2 A}};$$

$$\therefore \operatorname{cosec} A = \frac{1}{\sin A} = \frac{\sqrt{1 + \tan^2 A}}{\tan A}.$$

Also, from (3) $\cot A = \dfrac{1}{\tan A}$, so that the other five ratios are now expressed in terms of tan A.

15. Changes in the Magnitude of sin A. As A increases from 0° to 360° the magnitude of sin A changes. Let OR be the initial line, and let OP trace out the angle A. Suppose ROP is one value of A. Draw PM ⊥ to OR. Then $\sin A = \dfrac{MP}{OP}$.

Now, when A = 0°, OP coincides with OR, so that MP is zero. Thus, when A is 0°, sin A is 0. Again, when A = 90°, OP and MP both coincide with OQ, which is equal to OR. Hence, when A is 90°, sin A $= \dfrac{OQ}{OQ} = 1$. Also, as A *continuously* increases from 0° to 90°, *i.e.*, passes through *every* possible value between 0° and 90°, the length of MP continuously increases from zero to OP; so that $\dfrac{MP}{OP}$, *i.e.*, sin A, continuously increases from 0 to 1.



In exactly the same way we see that as A continuously increases from 90° to 180°, sin A continuously decreases from 1 to 0.

Next, as A increases between 180° and 270°, the revolving line passes through such positions as OP′. Evidently M′P′ is now negative, and since OP is always positive we have $\dfrac{M'P'}{OP'}$ negative; *i.e.*, as A increases continuously between 180° and 270°, sin A continuously decreases from 0 to −1.

Similarly, as A continuously increases from 270° to 360°, sin A continuously increases from −1 to 0.

Hence, *the sine of an angle can never be greater than* + 1 *and never less than* − 1.

16. Changes in the Value of cos A. The student can now verify for himself that as A increases from 0° to 90°, cos A decreases from 1 to 0. As A increases from 90° to 180°, cos A decreases from 0 to −1. As A increases from 180° to 270° cos A increases from −1 to 0. As A increases from 270° to 360° cos A increases from 0 to 1.

Hence, *the cosine of an angle can never be greater than* + 1 *and never less than* − 1.

17. Changes in the Value of tan A. Referring to the figure of Art. **15**, when A is 0°, MP is zero, and OM is equal to OP. Therefore tan A, or $\dfrac{MP}{OM}$ is zero. As A increases between 0° and 90°, MP continuously increases, while OM continuously decreases, hence, $\dfrac{MP}{OM}$ continuously increases. When A approaches 90°, OM becomes infinitely small, until, when A is 90°, $\dfrac{MP}{OM}$ becomes OP divided by an infinitely small quantity, *i.e.*, tan A is an infinitely great quantity. Thus, between 0° and 90°, tan A increases continuously from 0 to ∞.

Similarly, between 90° and 180°, tan A decreases from ∞ to 0. Between 180 and 270°, tan A decreases from 0 to −∞. Between 270° and 360° tan A increases from −∞ to 0.

H. J. ALLPORT

A Survey of the Chief Natural Economic Regions of the World and their Place in the World's Commerce. India's Trade.

NATURAL WEALTH OF NATIONS

HAVING studied the distribution of the chief natural commodities we must now turn our attention to the economic conditions of different countries. Commerce depends on one person or people producing more than they want of something which another person or people do not produce, or produce in insufficient quantities. The excess or defect of production may be due to natural conditions or to the stage of economic development of a people. For instance, most plants are confined to a particular zone—cotton, sugar, and coffee to the warm, tropical and sub-tropical zone, oats to the cool temperate zone. Again, coal is exported from Britain to the Baltic because there is practically no coal quite near the Baltic coast; but coal is exported from Britain to China, not because there is no coal in China, but because the vast coalfields there have not yet been properly opened up. It will be useful, therefore, to consider how countries may be grouped according to their natural products, taking into consideration the economic conditions of their inhabitants.

Zones of Different Natural Products. The first broad distinctions are between the hot or tropical, the warm or sub-tropical, the cool or temperate, and the cold or Polar lands. In each belt varieties occur according as the rainfall is heavy, moderate, or very scanty. The natural vegetation gives the key to these different divisions, and the products of each type of forest, grassland, or desert are discussed in previous articles of this course.

The Chief Trading Countries. In our own country, in most of Europe, North America, and European colonies, modern methods of cultivation, of transport and commerce have been introduced. Stock-raising, fishing and agriculture are carried on for the market, and the working of minerals and the development of manufactures are developed on a large scale. These countries may be further subdivided into two groups—those importing food and raw materials and exporting manufactured articles—such as Central and Western Europe and Eastern North America; and those largely exporting natural and cultivated products, and importing manufactured goods, such as Eastern Europe and European settlements in warm and cool temperate zones.

The Eastern Awakening. In Japan, China, and India, the soil is even more carefully cultivated than with us, but metal-working and manufacture by modern methods on a vast scale have only recently been introduced. The trade of these countries resembles that of the group last considered in that they still export natural products and import manufactures. The methods of agriculture are laborious, labour-saving machinery is little used, products are grown mainly for home use, manufactures and metal-working may be described as domestic, for the factory system has only recently been introduced. Japan is at present the most advanced of these countries, but India and China are following it.

The Poor Lands of the World. The poor lands around the Poles and the desert margins have too little natural wealth for exportation on a vast scale, but here and there, where rich mineral deposits occur, such as gold in Klondike, or where irrigation can be practised, as in Russian Central Asia, a dense and busy population is concentrated in districts usually of limited area. The lumber, etc., of the forest [pages 5297-8] and the animal wealth of the seas [page 5311] are the chief other commodities. The trade is one of export of natural products or minerals more or less worked up in exchange for manufactures.

The Rich Hot Lands. The rich grasslands of the hot belt have a denser population engaged in agriculture, pastoral pursuits, and even domestic manufacture. A considerable local trade is developed. Their exports are mainly natural products, for which manufactures are taken in exchange. They differ from the poor lands in possessing vast possibilities, and here and there, under European stimulus and supervision, are producing on a large scale—for example, bananas in the West Indies and cotton in most of the area.

The hot wet forests are much more backward. There is little agriculture or even domestic manufacture. The spontaneous products such as rubber, oil palm, coconuts, are exported in exchange for light cloth, hardware, and firearms. In the distant future these forests may become invaluable sources of supply of vegetable foods and raw materials.

The Study of Economic Geography. The first question to ask in studying commercial geography is what are the natural conditions of a country, its vegetation, its animal products, its mineral wealth? Next come considerations of density of population—how far the country can support the people, how far routes are opened up to allow its districts to communicate with each other and with other lands. These points have already been dealt with in the general geography.

The next consideration is the commerce of the land—how far it has commodities to export, and how far it must obtain necessaries and luxuries from outside its boundaries. From the outset the student is strongly advised to make use of statistical publications. It is not necessary to remember the detailed figures, but it is important to grasp the relative importance of the different exports and imports, and to try to understand what they mean geographically.

In the following sections such statistical tables will be freely used at first, and their significance pointed out, so that the student may become familiar with the examination of such tables for the purposes of commercial geography. Later, when he is thoroughly practised in this, it will not be so necessary to print many tables, but merely to refer the student to them in such annuals as the "Statesman's Year Book," the "Daily Mail Year Book" or "Whitaker's Almanack."

It is easiest to begin with the simpler conditions of the lands last mentioned, and to end our survey with the economic activities of the complex modern states of European peoples and their descendants.

THE COMMERCIAL HIGHWAYS OF THE WORLD

The ocean route distances are given in *statute* miles (69=1°) instead of the more usual *nautical* miles, or knots (60=1°), so that they can be correctly compared with those of the transcontinental routes.

Brazil as a Type of Tropical Lands. Let us select Brazil as one type of the hot, wet forest area, with open woods in the higher lands, and also at lower elevations, where it lies farthest from the equator. Some recent export figures are:

EXPORTS	Quantities		Values	
	1911	1912	1911	1912
	Bags.	Bags.	£	£
Coffee	11,257,802	12,980,303	40,401,206	46,558,079
	Kilos.	Kilos.		
Rubber	36,547,000	42,286,000	15,057,015	16,095,025
Yerba maté ..	61,831,000	62,880,000	1,983,209	2,102,568
Leather	31,931,000	36,255,000	1,798,781	2,011,820
Cocoa	34,994,000	30,168,000	1,641,381	1,529,842
Tobacco	18,489,000	24,705,000	965,357	1,434,371
Cotton	16,647,000	16,773,000	978,998	1,037,395

These may be divided into spontaneous and cultivated products. The most important of the natural products is rubber from the great forest, which has merely to be collected. The savanas yield grass for cattle, hides and skins come from the pastoral higher lands, especially of the south. Brazil has, however, many plantations the products of which are chiefly the alkaloid beverages—cocoa in the warm, wet parts of the north-east; coffee, mainly on the hills near the tropics, and yerba maté, or Paraguay tea, from the south. Finally, cotton, the fibre most used for clothing in the tropics, is grown in the north-east, but comparatively little of it is manufactured in Brazil. [See also page 3407.] In exchange for these, Brazil imports:

IMPORTS	1911	1912
	£	£
Machinery, apparatus, and tools. .	5,842,000	7,332,000
Iron and steel manufactures ..	5,473,000	6,851,000
Wheat and wheat flour ..	4,438,000	5,349,000
Cotton goods	4,905,000	4,044,000
Coal	2,788,000	3,846,000
Wine	2,362,000	2,601,000
Chemicals and drugs	1,242,000	1,455,000
Codfish	1,180,000	1,660,000
Kerosene and mineral oils ..	777,000	1,167,000
Jerked beef	967,000	936,000

As Brazil has so few factories, these are mainly manufactured goods. The next important class consists of products of the temperate zone and fish for food. Coal is required for railway, manufacturing, and domestic purpoess.

The Belgian Congo. The Belgian Congo [see page 3769] is another example of a country with like geographical conditions, but somewhat different economic ones. Its exports are as follow:

Rubber, £1,380,735; white copal, £255,394; ivory, £222,073; palm nuts and oil, £166,029; cocoa, £44,600. In addition, the exports of crude copper amount to £164,612, and of gold to £132,888.

Here is a land more recently opened to European influence. Spontaneous products of the forest play an all-important part, and cultivated plants yield but a small proportion of the total exports. The imports to the Congo are equally suggestive:

Foodstuffs and drink, £711,000; cotton tissues, £387,000; metals and metal manufactures, £294,000; machinery, £227,000; and clothing, £148,000.

Here the white man is even more dependent than in Brazil on supplies from Europe, whence practically all food and clothing are brought.

Typical Islands of the Hot Belt. Now let us take two islands where the systematic exploitation of the soil has progressed much farther than in tropical Africa or South America. From Cuba, in the West Indies, the exports for 1912 amounted to £30,580,685, of which sugar furnished 64 per cent. and tobacco 20 per cent. Of the remainder, fruits (pineapples and bananas) and iron ore are the most important. Timber is also a valuable export, the principal species being cedar and caoba.

The United States offers a ready market for the sugar, which is by far the most valuable crop, and takes about 84 per cent. of the exports from Cuba.

Tobacco, one-third as valuable as sugar, and in the form of Havana cigars, is sent all over the world, but especially to Europe and the United States.

In Java, in the East Indies, the chief exports are sugar (£11,184,000), tobacco (£3,409,000), tin (£2,776,000), coffee (£2,087,000), tea (£1,945,000), copra (£1,535,000), tapioca, pepper, rice, kapoc (used in upholstery and for making life-belts), and rubber. In both islands cultivated products far outweigh spontaneous ones in importance.

Possible Products of the Intertropical Zone. We may take the products of these islands as typical of the kinds of commodities which may be expected to be produced in larger and larger quantities from this intertropical region. In return, textiles, especially cotton, machinery, and hardware, and iron and steel goods of many kinds, luxuries of food and drink, especially wines, spirits, and beer, are imported, mainly from Europe and North America, but also from Japan, and, in the case of cotton, from India.

The commercial importance of this area may also be estimated by the population. The total number is comparatively small; and when we consider the stage of civilisation of large numbers of these people, we realise how small their powers of production and their demands for consumption must be.

Yet much land in the hot zone is fit for such cultivation as is practised in Cuba or Java or parts of Brazil. The total area of the hot belt is about half of the area of the globe. There are parts of this hot belt towards its margins, such as India and the south of China, which are well cultivated and densely peopled. The economic conditions of these old culture lands deserve a closer study.

The Lands of Southern and Eastern Asia. The eastern monsoon lands are partly intertropical and partly subtropical. The more sparsely peopled mountainous areas of South-east Asia may be classed with the regions just described. India and China, however, with their dense populations, require further consideration. In both there are vast fertile lowlands, which receive periodic rains in summer. Much of these lowlands is flooded annually, so that a layer of fresh soil is left which repairs the loss of fertility due to the crops of the previous season. There is, however, a great climatic difference between the two. India is hot at all seasons. Most of China has a well-marked winter, which is particularly severe in the north. This limits the period of cultivation in Northern China, and excludes all crops which cannot stand frost or are not annuals. Let us examine more closely the economic conditions of India. Before doing so the student should read again the remarks on pages 2525-2530.

Economic Regions of India and Ceylon. From an economic point of view we may divide India into the following districts: 1. The north-western mountainous land of Kashmir, pro-

ducing wool. 2. The north-eastern mountainous land of the Eastern Himalayas and Assam, with many tea plantations on the mountain slopes, and also with sal and other timber trees. Some rubber is collected in the lower Assam forest. 3. The irrigated Punjab, with wheat, millet, sugar-cane and some pulses. 4. The united provinces of Agra and Oudh, which form a transition from 3 to 5. 5. Bengal, the wettest and most fertile of the northern lowlands, producing rice, sugar-cane, opium, indigo, and jute in the deltaic region. 6. The Sind desert, with sheep, goats, and camels, yielding wool and hair, and also cotton in irrigated places. 7. The Northern Deccan, with cotton, wheat, millet, and oil-seeds. 8. The Central Deccan, with cotton, millet, oil-seeds, pulses, and sugar-cane to the south in Mysore. 9. The west or Malabar coast, producing cotton in the lowlands, sugar in the north, in Kathiawar, and teak on the forested slopes. 10. The east or Coromandel coast, producing cotton, palmyra palm-sugar, tobacco, in addition to millet, oil-seeds, and ground nuts. 11. Ceylon, with coconut groves round the coast, rubber plantations and ricefields on the lowlands, tea, cinchona, and cocoa on the hillsides, and rich plumbago or graphite mines. 12. Upper Burma, with teak forests and ruby mines. 13. Lower Burma, with ricefields, teak, and petroleum.

Exports of India. To Karachi, mainly by lines of the Indus basin, are sent wheat from the Punjab and some cotton and oil-seeds. Bombay receives from lines along the coast and descending from the Deccan the great supplies of cotton from Gujerat and the black cotton area of the plateau, whence come oil-seeds, opium, and wheat. It also exports cotton yarn and piece-goods from Bombay mills. The lines of the wider eastern coastal plains of the Northern Deccan converge on Madras, where cotton, oil-seeds, and rice from the easily flooded deltaic lands are exported. The greatest port of India is Calcutta, with the immense fertile plains of the Ganges and the hilly lands of Assam as hinderland. Hither opium is brought for exportation, and great supplies of jute, jute manufactures, rice, oil-seeds, and wheat. The plains of Burma furnish the rice and the hills the teak, which are exported at Rangoon.

Of the imports into India nearly 38 per cent. pass through Calcutta, 36 per cent. through Bombay, 10 per cent. through Karachi, 8 per cent. through Rangoon, and 7 per cent. through Madras. In the export trade, Calcutta again holds the first place with nearly 38 per cent. of the total outgoing trade; Bombay has 28 per cent.; Karachi over 10 per cent.; Rangoon 9 per cent., and Madras 3 per cent.

The Total Trade of India. The overland trade of India is small, owing to the mountain barrier, which makes communication difficult. The total seaborne trade of India, excluding Government stores and treasures, was, on the mean of the five years 1905-6–1909-10: Imports, 1,159,455,000 rupees; exports, 1,679,145,000 rupees, and re-exports, 34,665,000 rupees, while in 1912-13 imports were over 1,609,000,000 rupees, and exports over 2,458,000,000 rupees, of which less than 48,000,000 were re-exports. The overland trade is less easy to estimate accurately, but in 1912-13 was over 103,000,000 rupees' worth of goods imported and nearly 95,000,000 rupees' worth exported, mainly from and to Nepal and Kashmir. (A rupee is worth 15·4d.). The import trade of India consists of cotton manufactured goods, which are worth about one-third of the whole, and more than twice as much as articles of metal and metal manufactures, and of food and drink, which are next in importance. Machinery, railway plant, oils, clothing, and chemicals are other import items. The metals, notably absent from exports, are important among imports.

The Customers of India. From the above list it will be seen that at present the greater part of the imports can be supplied most easily from Europe, and that the exports, excluding opium to China, manufactures of cotton to China, Japan, and the East generally, and jute to wheat-growing lands as gunny bags, are products lacking in Europe. This is borne out by the table showing the origin of imports and destination of exports.

We may ask the question, How far is this trade permanent? Obviously, India can supply its people with food, but when the population is dense no food remains for export. For instance, Burma, with a far smaller fertile area, exports three times as much rice as Bengal, because the very large population of Bengal consumes most of the crop. Most of this Burmese rice goes to Japan and Straits Settlements. On the other hand, owing to the great demand for wheat in temperate lands, India produces much as a winter crop mainly for the foreign market, the cultivators living largely on millet. India has an advantage in sowing the wheat when the results of the northern temperate harvests are fairly well known.

In 1904, when the North American crop failed, the export from India was 25,500,000 cwt. Famine, however, has to be reckoned with, and the above figures may be compared with the 6100 cwt. of wheat exported to the United Kingdom in 1900. The increasing demand for raw cotton is likely to ensure an extension of cotton cultivation, while the efforts to suppress opium-smoking in China will greatly diminish the cultivation of the poppy.

VALUES OF IMPORTS AND EXPORTS IN THOUSANDS OF RUPEES, 1912-13

Country	Imports into India	Exports from India	Total
United Kingdom	1,014,411,390	606,516,255	1,620,927,645
Germany	103,033,995	284,633,145	351,667,140
United States	52,030,950	187,900,440	239,931,390
China	30,166,575	203,697,495	233,864,070
Japan	40,666,980	185,417,265	226,084,245
France	21,790,110	157,451,325	179,241,435
Belgium	30,434,175	131,350,305	161,784,480
Java	95,391,075	32,395,980	127,787,055
Straits Settlements	30,855,360	120,955,290	120,955,290
Austria-Hungary	35,275,320	72,521,520	107,796,840

India's poorness in minerals, especially in coal and iron in close proximity to each other, greatly hinders industrial development. The climate is unfavourable to great exertion in factories, and the quality of labour is not so good as at home. Hence, though wages are low, the cost of labour per yard is relatively high. Nevertheless, there is a steady increase in the number of factories and of the output of manufactured goods from India.

Ceylon. Colombo exports tea, coconuts, and graphite or plumbago. Rubber is being cultivated and will soon be important. Colombo is one of the great shipping junctions of the world, where ships from Suez in the north-west, the Bay of Bengal in the north-east, Singapore and the Far East, and Australia in the south-east, all meet.

A. J. AND F. D. HERBERTSON

Woods. Difficulties of Grain. Tools. Transferring the Design. Chip and Flat Carving. Relief and Intaglio Work. Bone, Ivory, and Horn Carving.

WOOD, IVORY, & BONE CARVING

ALL wood that is to be used for carving should be well seasoned, free from sapwood, knots, flaws, bruises, cracks, shakes, and nails, with straight grain and but little figure.

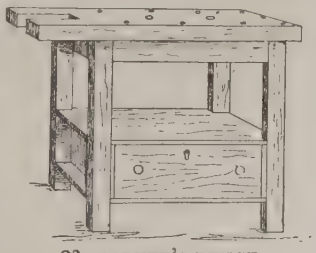
Some Suitable Woods. White deal, yellow deal, and American whitewood are soft and readily worked—too soft, indeed, for fine work, but affording capital training for the novice, who requires constant care and alertness in order to avoid accidents to himself and his material. Red deal is suitably soft, but the resins in which it is so rich clog the tools and make delicate work impossible. Plane does not split readily, and consequently can be carved into very great detail. Lime, pear, and sycamore are tougher, with nice easy grain. Kauri and Hungarian ash are both ideal woods for the carver of furniture intended for bed-room suites. Cedar is delightfully free, but very brittle. Walnut and American walnut are fairly hard, cut well, are durable, and take a good polish. Mahogany, in spite of its hardness and propensity for splintering, is not particularly difficult to carve, though the earthy salts it contains cause it to blunt tools very rapidly. Box, ebony, and cocoanut are close-grained, exceedingly hard and intractable, and only fitted for work for which unlimited time can be spared. Chestnut is tough, and rather troublesome to carve, though when finished, its colour, tone, and durability make it a formidable rival to oak.

CARVER'S TOOLS

1, 2, 3, and 4. Firmers 5. Parting tool 6. Macaroni 7 and 8. Spade tools 9. Gouge 10. Fluter or U-tool 11, 12, 13, and 14. Gouges 15 Moulder 16. Hey's saw 17. Mallet 18. Router 19. Carver's knife

The Value of Oak. Oak is universally admitted to be the favourite wood from which to fashion household and ecclesiastical furniture. The grain is a little tricky at first, but when once the carver has mastered its peculiarities, he will prefer it to all others, as did his ancestors, for it was in oak that their finest church work was executed; oak dower chests held their wardrobes; oak beds, benches, and settles rested their limbs; oak beams framed their dwellings; oak rafters supported their roofs, and oak panels furnished their rooms. No other wood withstands damp so well or improves so greatly with age. Besides the above, satin-wood, maple, bird's-eye maple, acacia, cherry, rosewood, olive, apple, ash, birch, beech, teak, camphor, Brazil-wood, bamboo, sandal-wood, and ironwood are all frequently employed. [See Timber in BUILDING, pages 216-19.]

The Mystery of Grain. On examining a transverse section of any exogenous wood it is seen to be built up of eccentric layers, around an almost central axis. The outer portion of each ring is denser than the inner. A longitudinal section reveals the fact that these layers can be separated from one another, permitting the wood to split lengthways. Each layer is composed of myriads of bundles of more or less fusiform cells, the long axes pointing in the direction of the growth of the tree. When wood is cut longitudinally the tool travels evenly between these fibres; when obliquely, they have a tendency to deflect it and guide it to a course parallel with themselves; when transversely, it continually changes the rate of its penetration, according as the soft or hard portions of a layer offer little or much resistance. Herein lies the crucial difficulty of wood-carving, for each species of wood and each separate plank presents its own peculiarities, which no amount of book learning or verbal description can possibly teach, and only constant practice can enable the student to master. No training will educate the beginner to overcome the mysteries of grain so quickly and pleasantly as chip-carving; it may not be the highest form of art, but it is executed with comparative rapidity, and the carver soon has something to show for his trouble. When, later on, he attempts the more advanced styles, he will find that he has already mastered most of the difficulties that they present.



20. CARVER'S BENCH

Tools. Carvers' tools differ very materially from those used by the carpenter and joiner, for whereas the latter are wrought from one plate of steel and another of iron welded together, and are sharpened on one side, the former have a steel plate between *two* layers of iron, and are sharpened on both sides, leaving a central cutting edge. Those chiefly used are given below.

FIRMERS. Shaped like a carpenter's chisel [1].

SKEW FIRMERS. A flat-bladed tool similar to 1, but with cutting edge set obliquely [2].

SPADE FIRMERS or SPATULAS. A spade-shaped flat blade welded to a square iron shaft. The edge is set either on the flat or skew [7 and 8].

ENTERING TOOL, FLAT-BENT FIRMER, or BENT GROUNDER. The blade has a double bend near its extremity to allow it to be used below the original surface of the panel. The edge is set flat or right or left skew [3 and 4].

21. CARVER'S SCREW

22. LONG DOG

PARTING TOOL or V. The name is descriptive, the cutting edge resembling the letter V. The shaft of the blade is either straight or up-curved [5].

GOUGE. The section of a gouge is an arc. It is said to be *quick* or *flat*, according as the radius is less or more than $\frac{1}{2}$ in. An extra flat gouge is hardly to be distinguished from a *firmer*. A gouge whose blade is $\frac{1}{4}$ in. across is quicker than one with a similar sweep, but wider [9].

FLUTER, VEINER, or U-TOOL. Similar to a very quick gouge, with an acuter curve than an arc [10].

MACARONI. In several shapes, either like a half-H or a truncated V; sometimes with rounded corners, sometimes with a curved base [6].

Gouges are made with *up-curved blades*, and also with *front* and *back bends* [11, 12, 13 and 14].

CARVER'S, or NORWEGIAN CHIP KNIFE. Has a blade with edge recurved towards the point which is in a straight line with the back, the whole being fixed almost at a right angle into a stout wooden handle [19].

ROUTER. A narrow *firmer*, driven through a flat piece of very hard wood at a steep angle, the edge projecting to the depth of the intended groundwork [18].

MOULDER, SINKER, or SCRATCH. A somewhat similar contrivance made from a piece of waste steel filed to the desired profile, and driven through a bar of wood furnished with a travelling guide like that of a *bar compass* or *trousquin* [15].

MALLET. A 5-in. stonemason's mallet, or a bottle-shaped *maul* are both preferable to a square-faced tool [17].

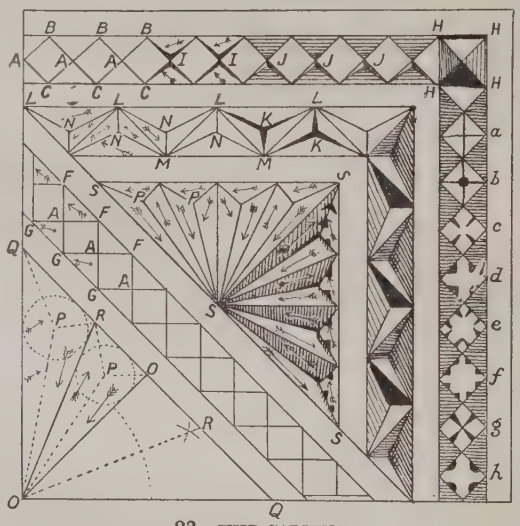
SAW. In addition to a small *tenon* and a *fret-saw*, a very useful model is that known as *Hey's saw*, such as is used by surgeons in operations upon the skull [16].

BENCH. A wood-carver's bench [20] should be very firm and heavy, with a solid top of chestnut or elm, 3 × 24 × 42 in. It should be high enough to permit the workman to rest his elbows comfortably upon it when standing. It is convenient to have it fitted with a deep drawer for tools, etc., within 9 in. of the ground. An invaluable adjunct is a good lever vice. The top should be perforated with a few holes to allow holdfasts, carvers' screws, and "long dogs" to be used.

CARVERS' SCREWS, used by screwing them into the under-surface of the panel to be carved, passing through holes in the bench, and fixing by a winged traveller. They offer no obstruction to the carver, but he must be careful to insert them opposite to some portion of the design not to be cut away, lest the protruding point should injure a cutting tool [21].

LONG DOG. A long screw furnished a-top with an iron cross-piece or *snib* [22*a*], and below with a *sycamore* nut [22].

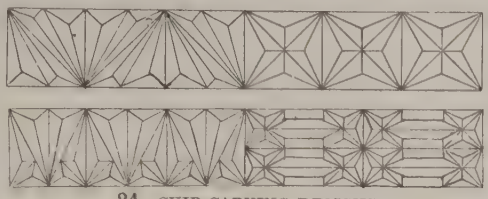
Transferring the Design to the Wood. Having determined upon the design, it must be transferred to the wood. If the carver be a good artist, he may sketch in the outline and leading features. He will find it a great assistance to rule the copy and the panel into corresponding chessboard patterns, filling in the details of the several squares; or he may superimpose a frame, strung with cross strands of silk or fine wire, above the drawing. By this simple device he can enlarge or diminish with great accuracy; or he may use a *pantograph*, or trace it with a style and carbon, calamine, blanc d'Espagne, or Prussian blue transfer paper, all of which he can easily manufacture by greasing unsized paper with spermaceti and rubbing in the required pigment. He may impress the design upon the wood with a style, pricker or tracing wheel. Time may be saved by cutting a stencil of one section of the design and stippling with thick size to which a pigment has been added. Lastly, he may paste the pattern itself upon the wood, always remembering that wet paper stretches, that wet wood warps, and that the pattern is destroyed for ever.



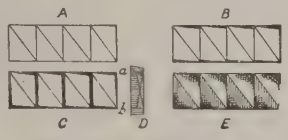
23. CHIP-CARVING

Chip-carving. The essence of chip carving, or spot carving, is that a more or less geometrical design is gradually built up by the removal of triangular or irregularly shaped chips. The following is the method of working.

Fasten a $\frac{3}{8}$-in. board of deal or whitewood, 10 in. square, flush with the right-hand corner of the bench, with the grain running right and left. Leaving a $\frac{1}{4}$-in. margin, set out a complete border of $\frac{1}{2}$-in. squares. Through each square draw two diagonals [23]. Select a skew firmer a trifle wider than half a diagonal. Grasp the handle firmly, guiding it with the left hand, till the point lies on an A and the edge along the line AB. Press the tool into the wood till the point has bitten to the depth of about $\frac{1}{8}$ in., the heel only just marking the surface. Repeat along each AB. The wood will be scored as at II. Turn the tool on its flat at such an angle that when entered along BB it will reach the bottom of the perpendicular cut by the time it reaches A. Lift out the chip BAB. The beds from which the chips are removed should appear as at JJ. Should the grain dip in places and lead the tool to bury itself too deeply change the direction of the cut from left to right. A slightly oblique thrust is less prone to be led astray by the grain than a straight forward one.



24. CHIP-CARVING DESIGNS



25. CABLE PATTERN CHIP-CARVING
A. Border *B.* First cuts *C.* Second cuts *D.* Section of second cuts through *a b* *E.* Appearance when completed

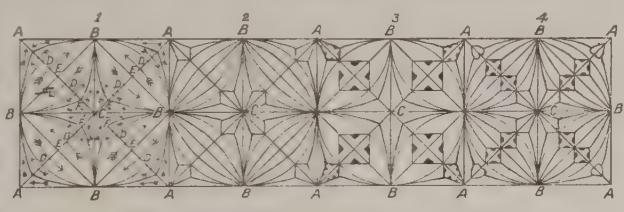
Continue till all the horizontal rows have been dealt with. Now treat the perpendicular rows similarly. Here again, avoid a straight cut; let the firmer travel diagonally across the grain, taking what advantage it can of the direction of the fibre. When all the sections have been removed, a border of flat diamonds will remain. These can be left plain, or their edges notched as suggested at *a b c*, etc.

Next attack the four corner squares. Sink from the centre to each H, and remove all the triangular sections, leaving an inverted pyramid. Or with a $\frac{1}{2}$-in. straight firmer sink along each HH; then with the skew carefully remove the top and bottom, and then the side chips, starting every time from the centre. This is rather troublesome, the difficulty being to get the edges of the pyramid regular. Leave a $\frac{1}{4}$ in. strap, and construct the diamond and straps as indicated. Remove sections AFF, AGG, working in the direction of the arrows. Set out the inner border LNM.

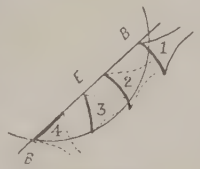
Proceed to sink as at KK. Remove all the sections, making each cut in the direction indicated by the arrows. Set out central star and four corner fans, joining each angle of a triangle to the centre of a circle inscribed within it. Sink along each of these lines, starting from P. Remove the sections as before.

Working with the Carver's Knife. Execute a similar panel on the lines suggested in 24, but work entirely with the carver's knife. A particularly effective border, known as the cable pattern, is figured in 25. Execute it with skew firmer and again with carver's knife.

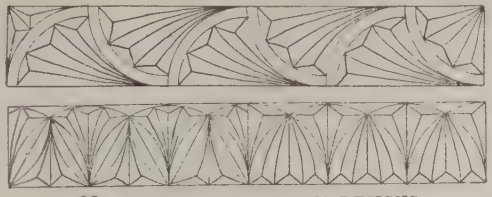
How Curves are Executed. By the introduction of circles a different knife-stroke is required. Set out a border 2 in. wide [26]. Divide it into squares AAAA. Inscribe a circle in each, joining the centres CCCC. Let fall a perpendicular BCB through each. From each centre A, at the distance AB, describe semicircles. Draw diagonals through every square. Sink the long axis BEB of each spindle BD, BD from $\frac{1}{8}$ in. deep at E to nil at BB. Remove the segments BDB with a flattish gouge, preferably a spade-shaped tool, concave surface upwards. Enter a point at B, thrust it along till it has reached E, when the direction of the cut is changed by swinging round the tool in order that its other point may finish up at the far end of the line BB [27]. Work with the arrows. Map out the rest of the design as indicated in 1, 2, 3, or 4 of 26. Whichever is selected, the segments bordering on the circumference of the circles must be removed with the concave surface of a very flat gouge, an ordinary firmer, or a knife. The variety of design is infinite, and each can be enriched with bands, fillets, grooves, veins, stippling, balls, hearts, crosses, interlacings and overlays [28].



26. CHIP-CARVING DETAILS AND DESIGNS

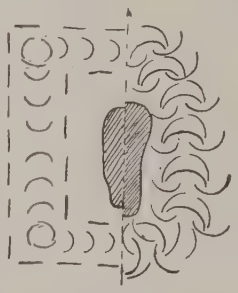


27. POSITIONS OF THE TOOL IN CHIP-CARVING CURVES



28. CURVED CHIP-CARVING DESIGNS

When under proper control, no tool is more useful to the woodcarver than the parting or V tool, which is illustrated in **5**; until thoroughly mastered, none other is so dangerous, both to the workman and his material; when blunt, none so utterly intractable. It is used in four ways.



29. GOUGE-ORNAMENTED KEYHOLES

Using the V Tool. If working in soft wood, grasp the handle firmly with the right hand, letting the butt rest in the hollow of the palm; seize the blade with the left, knuckles upward; bury one half to two-thirds of the cutting edge in the wood; push it onwards, on an even keel, keeping the same depth, guiding it with both hands, but forcing the blade onwards through the substance of the wood chiefly with the right [**33**]. Draw a few straight, curved, waved, and zigzag lines on a piece of waste wood, and endeavour to follow them with the V, ever keeping the guide-line midway between the *wings* of the tool. Next draw parallel lines at distances varying from 1-16 in. to ¼ in.

30. EXERCISE FOR V TOOL

Cut out the intervening wood, letting each wing of the V just touch the line. Next attempt circles. Beware of giving the tool a list to one side, especially when turning a sharp curve, lest the inside wing should bury itself and splinter the wood; rather press more heavily in the opposite direction. When one vein crosses another, the wood is apt to break away at the junction. Should there appear to be any danger of this happening, start the cross-cut from the point of intersection, and work away from it in either direction.

32. EXERCISE FOR V TOOL

In the second method, for delicate work, and for negotiating corners and curves, the back of the left hand is rested on the wood, the blade being guided by the thumb and two fingers, while all the pushing is done by the right [**34**].

Thirdly, if the wood be hard, the tool is grasped midway with the left hand, knuckles upward, and driven forward by repeated strokes with the mallet upon the butt of the handle, guiding the direction of the groove and regulating its depth quite as much by the impact of the blow as by the pressure of the left hand [**35**].

The blows may be given with the open palm of the right hand [**36**]. For many purposes the rapidity and delicacy of this last manœuvre cannot be excelled.

The Fluter, Veiner, or U Tool. What has just been said about the position of the hands, the employment of the mallet, and the "palm-tap" will apply equally well to the fluter, with one small exception: it is rarely advisable to sink the trough to its full depth with the first cut, unless the carver be an adept and quite certain of his touch; it is far safer to burrow out the hollow little by little, working between double lines.

Set out the border [**32**] on a strip of deal. Work

31. EXERCISE FOR FLUTER AND PUNCH

it with either tool, using the two-handed method. Set out the panel design [**30**] on a ⅝ in. oak board, carve it with the V tool and mallet. Try each with the "palm-tap." For making circular hollows with the fluter, split the wood at an angle of 45° at any point of the circumference; continue till the whole circle has been traversed and the loosened chips removed; then, with a single sweep, let the tool re-travel the whole distance, tilting it the while, that one arm may cut away the ridges which were left on its former journeys.

Drilling and Notching. For drilling small holes, such as "eyes" of leaves, hold the fluter perpendicular to the wood, rotating it rapidly between the open palms of the hands, at the same time exercising a slight downward pressure. It is

surprising how quickly a plank an inch thick can be pierced by this little manœuvre [37].

Notching is a favourite style of ornamentation, for which either the U or V is a suitable tool [10 or 5]. Drive a perpendicular cut into the wood to a depth of about ⅛ in.; then, re-entering the tool at the required distance from the convexity of the gash, let it sink deeper and deeper until the groove reaches the bottom of the first cut; a slight tilt inwards with each wing of the tool will free the chip.

33. POSITION OF HANDS WHEN USING V TOOL

The Punch. The design can be emphasised by stamping certain portions of the uncut surface with a punch [41]. Hold the punch firmly between the fingers and thumb of the left hand, in such a manner that the lower end of the tool may just free the panel; strike it smartly with the maul, that its pattern may indent the wood; rest the left wrist upon the bench, that it may offer sufficient resistance to enable the tool to recover its position between the strokes. Keep the punch constantly travelling in a haphazard, irregular fashion over the surface, since this gives a much more pleasing effect than if the indentations were parallel to one another. Do not use too sharp a tool—its duty is to punch, not to prick. Plain bands may be embellished with an occusional stamp with a circular, star, or dagger-shaped punch [42]. The keyholes of fifteenth-century chests were sometimes ornamented with patterns punched with the edge of a gouge [29]. Set out the design for an occasional table [31] on a piece of walnut; work it out with a fluter, or U tool, and four pointed punch.

34. USING V TOOL

35. THE MALLET TAP

36. THE PALM TAP

37. BORING "EYES" WITH FLUTER

38. THUMBING A FIRMER IN FLAT-CARVING

39. FORCING TOOL INTO HARD WOOD

Ambidexterity. When complete command over these tools has been attained, the student should learn to use them left-handed. The ambidextrous woodcarver has a great pull over a man who can only work right-handed; as the run of the grain varies, so can he change his tool from one hand to the other and follow it. In chip carving, especially, the time saved by not having continually to unfasten and refasten his wood, in order to turn it upside down, is very considerable.

Flat Carving. Flat carving consists in cutting away certain portions of the surface of the wood, leaving the untouched parts as a raised design. Transfer the Jacobean panel [48] to a white deal board 24 in. by 11 in. Follow as much of the outline as possible with a carver's knife or skew firmer. Hold the knife in the right hand, the edge of the blade pointing in the direction in which it has to travel. Let the point penetrate the wood to the required depth. If working away from oneself, or from right to left, push it along with the left thumb, guiding with fingers of the left, and pulling in with the right hand when in a contrary direction. Avoid cutting against the grain, and follow the course of the arrows. The skew firmer may be used similarly, and with the same precaution [38], or a straight firmer, if it be tilted sufficiently to allow the front point to clear the surface.

If the wood be hard or the design complicated, the outline must be followed by selecting suitable tools to fit its varying contours, these being driven home with the mallet or forced into the wood by throwing the weight of the body forward upon them [39]. Slope the cut slightly outwards from the pattern. Frequently the margin will be found to present a rounded edge, or to show the ridge where two cuts may have overlapped. The latter may be overcome by selecting gouges of a rather flatter sweep than the convex curve to be travelled, or a trifle quicker for a concavity, and by letting each cut overlap its neighbour; the former by running a trough with a V tool within 1-16 in. of the outline. When the firmer or gouge is used later it will be found that the wood will break away into this, leaving a sharp margin on the other side. Again, when firming in the vicinity of sharp points or weak places, the tool should be entered at a wide

40. USING GROUNDER OR FLAT GOUGE

angle at some little distance from the outline, then nearer at a lesser angle, and so on, until the dangerous point is reached safely [45].

Difficulties Presented by Grain. Superfluous wood must be removed to a given depth in the intermediary spaces, which is accomplished first with quick gouges, then with flat gouges, further to level the floor, and, lastly, with flat grounders. In doing this, the difficulty of grain will again obtrude itself, for it seldom runs exactly parallel with the surface, but dips either one way or the other, leading the carver to bury his tool too deeply, splintering the wood, or undercutting the pattern. To overcome these dangers, several precautions must be taken. (1) When first fixing the panel on the bench, look at its edges and place it so that the grain may trend upwards from right to left; (2) should it be irregularly wavy, constantly change the direction of the cut to follow its upward curve; (3) use very sharp tools; (4) support the shaft of the blade with the right hand [40]; (5) always work a trifle obliquely to the grain; (6) glide the tool along with an onward and at the same time circular sweep, slicing the wood rather than making an absolutely straight cut through it; (7) make sure that the firming cuts are of their full depth, especially in the neighbourhood of weak places and sharp points.

41. CARVER'S PUNCH

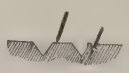
43. EXAMPLE OF DIAPER WORK

44. THE COURSE OF THE STROKE WHEN GROUNDING



45. STROKES IN FLAT CARVING

46. ROUNDING ON THE FLAT

A Much-abused Tool. The *router* [18] is invaluable for rapid grounding. Hold it tightly with both hands and push it backwards and forwards with gradually increased pressure, letting it travel over the entire ground until its flat under surface rests everywhere evenly upon the face of the panel. Finish corners, into which it cannot penetrate, with skew grounders. Most manuals decry the use of this handy little tool in no unmeasured terms. After all, it is the carver's object to remove waste wood; and though it is perfectly right he should learn to do this neatly, with very flat gouges and grounders, there is no reason why he should waste valuable time over an unimportant detail of the work which he can accomplish twenty times more quickly with the use of the router than without it.

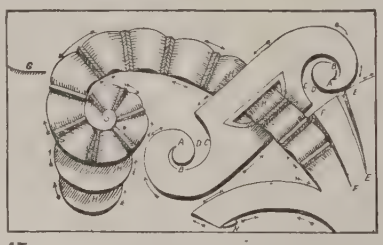
When a perfectly level floor has been smoothed out, it may be stamped with a punch to throw up the pattern into stronger relief. It was not an uncommon practice in the fourteenth and fifteenth centuries to paint or gild the ground, afterwards indenting it with geometrical designs or diapers. Occasionally it was left rough intentionally, the contrast with the polished surface of the design answering the same purpose as stamping. By bevelling the top edges of a pattern at a wide angle and slightly undercutting the bottom ones, a pleasing effect of light and shadow, suggestive also of greater depth, is gained.

Sloping a Flat Surface. The next step forward is to slope the flat surface of the pattern. In its very simplest form, folds, turnovers, and interlacements are suggested by a touch of the firmer or V tool; or it is scored with the veiner or U to simulate the veins or irregular margins of leaves; or lowered in places to imitate the appearance of an overlay.

Set out the Jacobean panel [49]. Firm the outline of the outer shield and ground out as before, following the course of the arrows [44]. Now carefully firm the inner shield, lower to $\frac{1}{8}$ in. in its immediate vicinity, then with very flat gouges gradually merge the depression into the flat surface of the design, smoothing finally with broad grounders. Sink with a flat firmer or gouge at AA to 1-16 in.; then, starting from BB, slope down to the bottom of the cut.

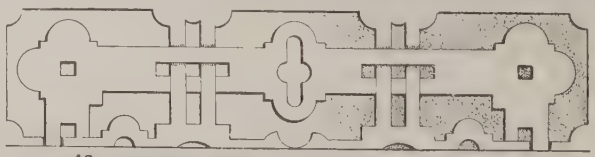
The inner line on the border of the top shield is made either with a tiny V tool or by simply scoring the surface with suitably shaped tools.

Ribbon wavings introduce another modification—namely, rounding on the flat.

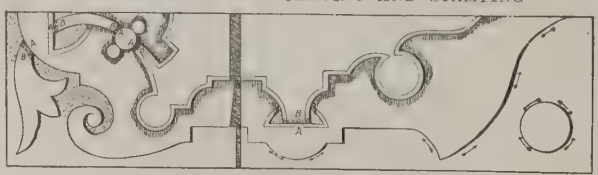


47. JACOBEAN ROUNDING ON THE FLAT

Rounding on the Flat. Transfer the design to a panel of white deal [47]. Firm the outline as far as possible with the carver's knife or a skew firmer, following the direction of the arrows.



48. JACOBEAN FLAT CARVING AND STAMPING



49. JACOBEAN SLOPING ON THE FLAT

Enter a narrow parting tool at A, let it gradually bite deeper as it follows the sweep of the volute until it reaches B, keeping it thus far upon an even keel. Now tilt it gradually to the left, that its right wing may be nearly upright by the time it reaches C. Return to B and tilt to the right, that the other wing may be almost perpendicular at D. Start from these points to firm out the rest of the scroll.

Cut E with V tool. F is only half a groove. The ribbon side must be firmed and the shape trimmed down with a very flat gouge. Ground out as before. (In the original panel the ground sinks gradually from the margin, only reaching its maximum depth of ½ in. from it, as at G.) Sink with a firmer or gouge at HHH, slope down the surface with a wide firmer, merging it into the flat. With suitably shaped gouges make perpendicular cuts in the spiral lines, starting from O. Now attack the ribbon. This can be accomplished in two ways. If the slope be with the grain, sink two perpendicular cuts where indicated, and shave down to the bottom of them with a broad firmer, starting with the blade nearly flat at the crest of the curve and getting more and more upright as it reaches the bottom of the furrow [46]. If the slope be against the grain, a macaroni can be used, or a V tool, which, after the first cut is made, can be tilted on one side and made to model down the fold in the ribbon.

Diaper Work. As the name suggests, diapers are series of repeated patterns contained in diamond-shaped compartments resembling the designs seen upon old napery. This style of wood decoration is closely allied to flat carving, and can be executed in two entirely different ways. Set out the diaper [43]. Cut perpendicularly along the outline with accurately fitting gouges; next lower the groundwork by hammering with broad, blunt punches, leaving the pattern in relief. The disadvantage of only depressing the ground and not removing it is this: wood that has been compressed will regain its former shape when moistened; thus hot water spilled on a diaper-ornamented tray would obliterate the design. If, instead of punching the ground, the pattern itself be lowered and the whole surface planed level, the design will reappear in relief if the wood be soaked thoroughly, only requiring a touch of the tool here and there to sharpen up the outline. Naturally, the relief is low, but this style of work does not readily lend itself to any other treatment. Great care must be taken to punch evenly, that the fibre of the wood may not be injured, for should this occur the pattern would not start up again when required.

50. SWEEP STROKE, FIRST POSITION

51. SWEEP STROKE, SECOND POSITION

Incised Carving. Incised work requires little technical explanation, for its details are similar to those of flat carving, from which it differs in only one particular—the design is formed by the portions removed, instead of by those which are left. To show it up more distinctly, colour can be run into the cuts with a fine brush, or they can be filled up with lacquer, and the whole scraped perfectly level and polished.

Sculpture d'Appliqué. Flat and incised carving, as well as diaper work, can be imitated easily by what is called *sculpture d'appliqué*, or applied overlays. Several thin sheets of wood are superimposed and the pattern fretted out; these pieces are next fixed in the required position with glue, the groundwork punched down, and the whole finished by paring down any rough edges that may obtrude themselves too vividly.

CARVING IN RELIEF

We now come to the most interesting of all styles of wood-carving, which consists of rounding down the surface to make it look like a natural object, whether a leaf, an animal, or a landscape.

A Panel in Relief. Set out the panel on white deal [52]. Firm the outline as usual. Ground out and complete the lozenges and ribbons. Sink the grooves BBB between the leaves to their full depth with a V tool. Leaning the tool first to one side and then the other, rough out the curved surfaces. With a flattish gouge model it still more perfectly, furnishing each leaf with a double convex contour, working all the margins to nearly ground level and letting each blend at its root with its fellows. It is better not to attempt to smooth the work piecemeal at this stage. Rather strive to get the general effect as a whole; then, and not till then, add the finishing touches with gouges that more nearly fit the curves.

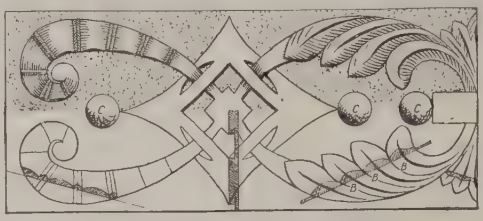
Now chip down the N.E., N.W., S.E., and S.W. corners of the balls CCC (if we may apply the term "corner" to a circular figure); next, with the concave surface of a flattish gouge, lower the wood N. and S. nearly to ground level; with a tool whose radius is nearly as quick as the circumference of the ball, round it off with a series of sweeping strokes, never making them quite in the direction of the grain, but with a forward, gliding, rotating, and ever-downward movement of the tool, so that the butt of the handle describes an upward spiral sweep.

The Carver's Freehand Stroke. It is impossible to devote too much time to the acquisition of this particular stroke, which is to the carver what freehand is to the artist. An adept will produce excellent effects with a turn or two of the wrist, while the amateur will flounder about trying to round off a figure by nibbling away at it with straight, pushing cuts. Added to this, its employment reduces the troubles caused by grain to a minimum.

Having studied the effects of the sweep stroke made with the concave surface of the tool, the reverse must be practised. Again a remarkably bold design is selected [54]. The general moulding is too well indicated to require any explanation; it need only be said that the original fifteenth-century font from which it is taken is only carved to the depth of about ⅛ in., the delusive appearance of solidity being suggested by broad bevels and slight undercuts.

The Reverse Freehand Stroke. Firm the outline and ground out as usual. Rough out the twisted leaf. Take a gouge with an arc corresponding to the curvature of the leaf, and not more than ¼ in. wide. Let the back of the tool rest nearly flat at A, A^1 [50 and 54]. Sweep it onward with a double curve that leaves the handle

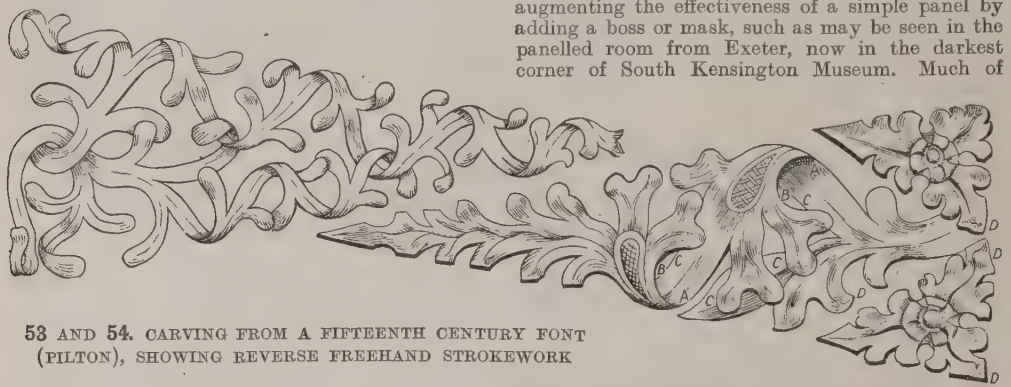
perpendicular and the blade at right angles to its first position by the time it reaches B, B^1 [51 and 54]. Do this with a continually gliding cut, so that whereas at A^1 the portion of the edge nearest the carver had most of the cutting to do, by the time it has reached B^1 it is practically free, and the other end of the blade is making the final downward cut. If too quick a gouge be used, an awkward-looking notch is left at the tail of the stroke; if too flat a one, it will probably hitch in the wood half way through the sweep. If the gouge be too small, the manœuvre will have to be repeated once or twice; if it be too large, the feat is almost impossible.



52. JACOBEAN RELIEF CARVING

such as are shown in 56, is simply a matter of combining these several methods. If a man can carve a single leaf or petal, he can, with patience, execute an entire flower. He should seize every opportunity to visit workshops, and watch how the trick is done; he will learn more in half an hour by so doing than in half a lifetime from manuals.

Modern Fakes. Relief carving nowadays is frequently "faked" by gluing a fret of the design to the panel and rounding off afterwards. This saves all the trouble of laboriously reducing a large portion of the surface to ground level. A more legitimate application of this was the practice of augmenting the effectiveness of a simple panel by adding a boss or mask, such as may be seen in the panelled room from Exeter, now in the darkest corner of South Kensington Museum. Much of the work executed by Grinling Gibbons's pupils and imitators was not true carving but *appliqué*. Many of the elaborate Devonian mantelpieces, decorated with flowers and drooping sprays, have had each leaf, stem, and flower carved separately, glued into position, touched up with putty, and finished off with paint. The French brought this style to great perfection, and adopted *sculpture à la scie* for the reduplication *ad infinitum* of floral wreaths and garlands. Further particulars will be found in "Sculpture sur Bois," one of the *Encyclopédie-Roret* series.



53 AND 54. CARVING FROM A FIFTEENTH CENTURY FONT (PILTON), SHOWING REVERSE FREEHAND STROKEWORK

Round the outside of the turnovers. Leave the edges of the leaf high, except at CCCC, where they must be lowered almost to ground level. The notches are cut with gouges held on the slant, bevelling one side and undercutting the other. Model the wavings of the leaves with gouges, noting particularly the rich double wrinkle at DD. Round off the balls, hollow their sockets, and complete by carving the bosses around them, and adding the veins with a V tool.

So all-important are these sweep-strokes that a second example has been figured with more numerous but smaller turnovers [53].

Knowledge of Clay Modelling and Shading. Should doubts arise as to how a subject should be treated, model it first in clay or Plasticine. If this be done now, it will be noticed that many of the folds in the copy are out of drawing. This is a common fault, for the carver is not always a first-class artist, and the medium he works in is not the most tractable. So useful are models at this stage that a course of modelling in clay should invariably precede that of carving in wood; the student should also be able to convert an outline drawing into a shaded study [see pages 3057 and 4909].

55. JACOBEAN PANEL MOULDING

Mouldings and Friezes. For mouldings and friezes the pattern is generally a repeat, and may run either vertically or horizontally. An easy example [55] of the former, taken from the same source as 45, 46, 47, 50, and 52, is given. The shaded portion shows the section. Run out a strip of oak with the moulding plane. Stencil the pattern on the wood. In firming the outline, the tool should always be pointed at the centre of the circle of which the face of the moulding happens to be the arc; by this means a clean edge, throwing a pleasant shadow, is ensured. At the extremities of the chord, AA, let the ground die away to the level of the surface. Vein with V or fluter. Drill the small holes with a very quick gouge as shown in 37 [page 5553]. Saw down at CC to the level shown in the section at BB, with a Hey's saw;

The More Complicated Designs. Having learned to vein, flute, firm, ground, slope, round, and turnover, the execution of more complicated designs,

round the balls and the ends of the bolsters as described. When cutting mouldings to occupy a horizontal position, this fact must be remembered when the work is on the bench. Take, for example, the familiar "egg and tongue." The sinking cuts, which are necessary to free the wood scooped from the hollow in which the egg lies, must be parallel with the horizon, and each upward sweep must meet it at right angles.

Flutings of pillars and pilasters may be carved with gouges, though it is far easier to run them out with a moulding plane or a travelling *bur*, leaving the carving tool nothing to do but to trim up the extremities of each. Spirals, which were formerly carved with gouges from start to finish, are now simply turned on a lathe.

A symmetrical twist may be easily obtained by winding a strip of paper, down the centre of which a line has been drawn, round the post to be carved, and marking the wood at its edges. Sink a furrow along this line with a V, keeping it on an even keel, and always at the same inclination to the axis of the cylinder. It is most important that this groove should be the same depth throughout if the post is of the same thickness all the way up, or taper gradually should it do likewise. Rough out the curves with flat gouges from the bottom of the furrow to the central line on the paper. Smooth with a gouge that is just a shade flatter than the curve of the spiral; this will give more play, and is less likely to get hitched than one which fits exactly.

56. PANEL IN RELIEF CARVING FROM A SIXTEENTH CENTURY ITALIAN MARRIAGE COFFER

Intaglio Work. Still another method of ornamentation is *deep, intaglio*, or *die sinking*. This is the exact reverse of relief carving, for the surface remains plain and the pattern is sunk. It is quite easy for any one who has been accustomed to relief work. The main features of the design are scooped out with bent gouges, details are added with quicker tools, and veins added last of all. It is of great assistance to the carver if he takes a squeeze of his work in Plasticine from time to time, in order to judge of the general effect. By disarranging the lighting, and causing shadows to fall in a contrary direction, a casual glance will receive the false idea of relief.

The Value of Keeping Records. Whenever possible, copies should be taken of good work. Putting on one side the obvious methods of sketching and photography, this may be done with a "squeeze." Oil the panel well, and proceed to cover it with sheets of very wet paper, pressing them thoroughly into every crevice; add layer upon layer of coarse brown-paper soaked in size or very thin glue. Squeeze out all superfluous moisture. Leave in position to set sufficiently well to permit of removal without danger. When this is dry, plaster of Paris casts can be obtained from it, or others having the appearance of wood itself by using a mixture of equal parts by weight of gelatine, wood sawdust, and phosphate of lime, moistened sufficiently to make into a stiff paste. Leather well soaked in hot water may be used, or a lump of soap, clay, or putty. Flat carvings may be "rubbed" with heelball or blacklead. This procedure is inapplicable to relief; still, a very good general idea of a panel can be obtained by the aid of a newspaper and a rather greasy rag. Press the paper down on the pattern, gently moulding it as much as possible with the fingers. On going over it with the greasy rag, the printing-ink will be smudged most wherever the relief is highest.

Work in the round is erroneously believed to be the most difficult of all styles to accomplish; in reality, it is nothing more than panels in relief carved on both sides. To minimise labour and to prepare the block, it is useful to take a profile of the copy with a strip of lead or malleable zinc. Apply this to the wood and pencil the outline. Take the opposite profile and transfer as before; then treat the sides similarly.

Carving in the Round. Remove with the saw as much of the waste wood as possible. Next whittle away superfluous material with mallet and gouge, proving progress with the metal guide or with callipers. Should any detail cause anxiety, model it over and over again, or work it out on a soft piece of wood. It is better to devote a few minutes to this than to waste the labour of weeks by perpetrating an irremediable error. Take off too little, rather than too much; superfluous wood can be removed, but additions are not so easy.

If he should be nervous about starting—and most novices are—let him begin on some ridiculously easy task, such as sharpening a pencil very neatly or carving animals such as those in a Noah's Ark. Afterwards he may try a poppy-head ornament, which he will find to be nothing but two studies of foliage in high relief placed back to back. The human figure and drapery are the most advanced style of all, just as is the case with relief, but the student will find it far easier to hack out a head or other figure-work in high relief than in low relief.

Tracery and Perforated Work. Tracery and perforated work is an advance upon fret cutting. The ground is entirely removed, leaving lights. It presents no difficulties to the good wood-carver, but it does not pay him nowadays to execute it. Modern machinery, with its lathes, planes, bits, and burs, can rip out tracery mouldings in a hundredth part of the time in which an expert workman can carve it; so with panel reduplication by mechanical means. It is wonderful to watch a species of glorified pantograph, armed with a

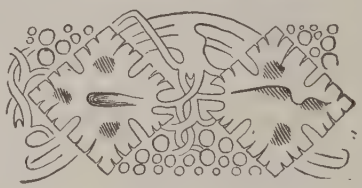
revolving bur, copy the design with hardly any manual assistance; but it is not wood-carving, and its servile imitation destroys half its charm.

Foliage. Veins of leaves are frequently carved in relief, instead of being sunk with a V tool or fluter. Twin furrows are run along with a V, leaving a medium ridge. The surface is worked down to the foot of this, which is trimmed to shape, tapered at its extremity, neatly joined at its branchings, and made to die away into the leaf stalk. The macaroni is a handy tool for this work, though it cannot be used close to a junction.

Though the flora of the wood-carver often bears but slight resemblance to that of the botanist, there are certain well-defined points common to each. Thus, veins, though showing as depressions on the upper surface of a leaf, appear as ridges below; remember this when treating a turnover. Noting the general characteristics of a plant, the student will the better appreciate the skill with which the mediæval artist selected and treated his subjects, and will see why it was that the lily, vine, thistle, oak, Passion flower, poppy, dandelion, rose, and, above all, the acanthus [57] were such universal favourites, and why the coarse and perishable nature of his material led him to limit his efforts to purely decorative adaptations.

The Vine and the Rose. The vine, not only because of its adaptability for ornamental purposes, but also because its religious symbolism, was constantly utilised in ecclesiastical architecture. The carver treated it in two distinct ways. Sometimes the leaf was inscribed within the limits of a symmetrical pentagon, its four eyes and the point of junction with the leaf stalk being arranged at the corners of a similarly shaped, but inverted, figure. At other times the leaf was placed within the area of a square or lozenge, as may be often noticed on the friezes and crochets of late Gothic work [58]. The thistle and dandelion are adapted to follow the lines of acute-angled triangles. Both are invaluable for filling in odd corners of tracery.

57. ACANTHUS LEAF DESIGN



58. VINE CARVING IN ATHERINGTON CHURCH, DEVON

Ivy falls within the lines of a pentagon, and occasionally those of an isosceles triangle.

The rose is conventionally depicted as a symmetrical five-petalled flower, each petal furnished with a fold-over having a bracket-shaped edge. A common sixteenth-century ornament was the Tudor rose, the union of the Houses of York and Lancaster being symbolised by the exhibition of both flowers in one boss, one superimposed upon the other, their petals alternating.

The Oak Leaf. Perhaps no other leaf had so many liberties taken with it by German carvers as the oak. They more than conventionalised it; they exaggerated, elongated, stunted, twisted, and folded it, till it became almost unrecognisable. They left it with widely indented margin, rectangular lobes, rugged and misshapen, stunted, gnarled, and bent like its parent tree, and yet effective and picturesque.

The acanthus [57] is a characteristic feature of Renaissance design. At first sight it appears a difficult and complicated subject, but on dissecting its structure it is found to be contained within the limits of two concavo-convex lines, which start from a common point, separate gracefully, and finally coalesce, the leaf bellying and swelling between them. This simplicity of outline is now broken by subdividing each leaf into a number of lobes, the junction of each with its fellow being marked by an "eye." Each lobe in turn is deeply serrated. A vein runs down the centre of each lobe, and pipings start from every eye, all losing themselves at a common point. Whether viewed in full or in profile, its main lines are always the same, never parallel, never crossing, but each a graceful curve radiating from a common point, and strictly subservient to an outline of the greatest beauty and simplicity.

Finishing and Ageing. It cannot be impressed too strongly upon the novice that sandpapering carved work to "make it look smooth" is an unpardonable crime. A few touches with the scraper or rubbing down with a bone are bad enough, but "papering" is the rankest of all heresies. There is nothing to be ashamed of in tool-marks, for at least they show the work is genuine, hand-wrought stuff.

To keep the carvings clean, light woods may be given a thin coat or two of "egg-shell" varnish; oak and chestnut should be treated to a soaking in boiled linseed oil, followed by plenty of "elbow-grease," using a stiff brush. Beeswax and turpentine should be avoided; they clog the corners of the work and destroy its sharpness. Most other hard woods may be French-polished.

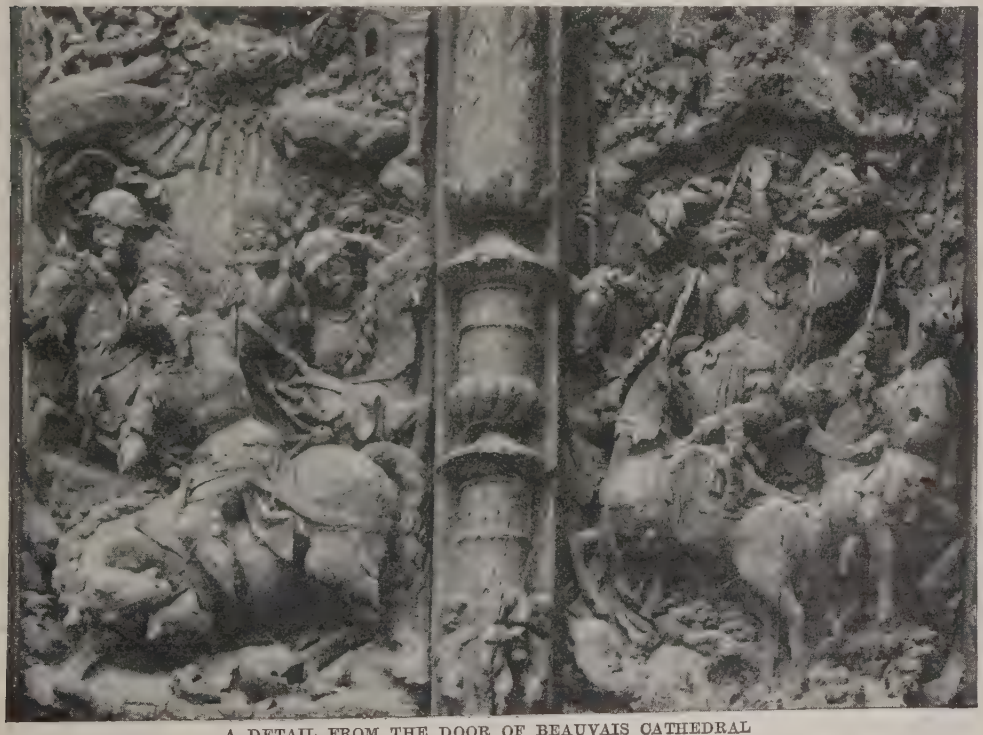
It is frequently necessary to stain new wood in order to make it match older work. Apple, pear, and box can be aged with a weak infusion of saffron; lime, ash, kauri, and whitewood with turmeric or a solution of chloride of tin; mahogany with Brazil-wood. Oak can be slowly darkened with a 2 per cent. solution of bichromate of potash to which ¼ per cent. of dilute nitric acid has been added. The process takes a few months, but the tone gained is particularly rich and warm. Veining and figure-work can be brought into strong relief by treating first with a weak decoction of madder, and, when this is dry, painting with a solution of acetate of lead.

Blue-black is attained by a decoction of oak galls, followed by a solution of green vitriol; jet black by a decoction of oak bark and then perchloride of iron; purple-black by log wood; brown-black by madder and acetate of copper.

Fuming. Oak, and other woods in a smaller degree, can be darkened very rapidly by exposing them, in an airtight box or cupboard, to the fumes of ammonia; but the weaker the dose and the longer the time allowed, the better the result. Storage for several years in a badly ventilated stable loft imparts a tone that cannot be equalled by any other method.

Wood-carvings may be preserved from the ravages of worm and rot by fumigating with calomel, formalin, or corrosive sublimate, by dressing with a solution of alum or of waterglass, or, best of all, by impregnating the panel with hard paraffin under heavy pressure at a temperature of about 180° F.

THREE FIGURES ON A DOOR AT ST. SAUVEUR CATHEDRAL, AIX



A DETAIL FROM THE DOOR OF BEAUVAIS CATHEDRAL

BONE AND IVORY CARVING

The presence of carved and engraved bones among the tertiary deposits of Europe and America constitutes the strongest link in the chain of evidence that connects man with this remote period [see pages 156 and 158].

Bone Carving. On account of the hardness of its outer layers and the cancellous structure of the inner, deep carving is not suitable to this material. Having sawn the bone into convenient slabs, rough out the design with the parting tool and very quick gouges; rough carve with flat gouges and firmers, finishing with the assistance of rifflers and files. Sandpaper then comes into play to remove scratches and tool-marks, the whole being finally polished with the help of putty powder.

Bone is easily dyed; it is even possible to impart a red colour to it during the lifetime of the animal by feeding it with madder (*Rubia tinctorum*). Bone is used as a cheap substitute for ivory for knife-handles, chessmen, thimbles, and other small articles, but it soon discolours, and the comparative coarseness of its grain renders it useless for the production of delicate objects.

Ivory Carving. The antiquity of this handicraft is also undoubted, for, like bone carving, it dates back to prehistoric ages.

Ivory is a fine-grained, hard, dentine-like substance composing the tusks of both the African and the Indian elephant, together with those of the walrus and the narwhal. The molars of the elephant yield a less dense variety, and those of the hippopotamus a peculiarly hard kind which was used by dentists. All the above are known as green or live ivory, distinguishing them from the white, dead, fossil, or Siberian ivory obtained from the remains of the extinct mammoth. The density, toughness, elasticity, durability, colour, and beautiful figure of ivory, its absence of appreciable grain, and its capacity for receiving a high degree of finish, eminently fit it for the carver's hands.

The Tools for Ivory Carving. The tools used for carving ivory are similar in character to those of the wood-carver, but smaller and stouter, with less tapered edges, like turning and engraving tools. The design is drawn upon the ivory in Indian ink, as much as possible of the surface is removed with the saw, the pattern is grounded out, and the contours roughly hacked into shape. The ordinary cutting stroke is too tedious to be of practical service. Waste is removed more quickly by holding the tool upright and advancing first one corner of it and then the other in a zigzag fashion, exerting firm pressure the while, nibbling the ivory away little by little. Drills and tiny points are next used for the deeper portions, and files for the shallower. Indeed, the file is such an important tool that "ivory filing" would be a more appropriate term for the art than "ivory carving." Ivory is more cheaply worked by worrying away its substance with revolving burs and drills.

Polishing, Engraving, and Repairing. The work is polished in three successive stages: (1) No. 0 glasspaper; (2) putty powder, pumice, or fine siliceous earth; and (3) a revolving brush fed with whiting and water. Ivory may be easily engraved, the pattern being rendered visible by rubbing in Indian ink or indigo, and papering the surface to bring up the lines clearly and sharply.

Broken ivories can be repaired with fish glue, provided the broken surfaces are not greasy, in which case cleanse them with sulphuric ether, alcohol, or benzene. Warm both fragments, apply as little glue as possible, and exert firm pressure till thoroughly set. Ivory dust or shavings mixed with fish glue may be used for building up bruises, chips, or deep scratches. Ivory carvings are apt to discolour unless exposed freely to both light and air.

Imitation and the Forgotten Moulded Ivories. Very fair imitations of old ivories may be made by covering carved wood with three or four coats of very pale chrome enamel, re-stamping the groundwork, and flooding the depressions with Vandyke-brown; or by making casts in a creamy-yellow plaster of Paris, boiling them in spermaceti or hard paraffin, stippling the ground and lining the furrows with brown, finally adding fine black, wavy strokes with Indian ink to simulate the cracks of the original.

Ivory may be made plastic by dissolving its earthy salts with phosphoric acid; on the other hand, when brittle and friable from age, it may be toughened by boiling in gelatine.

There is little doubt it was at one time possible to soften ivory so as to allow of its being squeezed or moulded into sheets of considerable size. Unfortunately, this is a lost art, for none of the recipes which have been preserved have proved successful.

Ivory Substitutes. The curiously hard seeds of the *Phytelephas macrocarpa* are used as a substitute for ivory; the absence of the characteristic "engine-turned" figure of genuine ivory at once proclaims this substitute.

An artificial ivory known as bonzoline is supposed to be a mixture of celluloid and some very fine mineral earth.

Horn Carving. Ox and buffalo horns are chiefly used for this purpose, though rhinoceros horn is occasionally ornamented as a curio. Ram's horn is so decorated by Nature that further treatment is superfluous. Horns of deer are really deciduous bones, and, with the exception of their being utilised as knife and cutlery handles, are generally better adapted as decorative objects when uncarved and arranged in pairs.

Horns may be carved with ordinary wood-carving tools, but owing to the smoothness, roundness, and natural greasiness of the surface, it is not always an easy matter to get the tool to bite. Fortunately, horn can be softened by boiling. The carver, therefore, overcomes the difficulty by letting a jet of steam play on the horn, though he has to be careful not to allow it to remain subjected to a high moist heat for long at a time, lest the natural cement which binds together the bundles of fibrous hairs of which it is constructed should be decomposed.

Working Difficulties. The carver also has to exercise considerable ingenuity in fixing his work firmly. Sometimes he will be able to keep it steady in a vice well padded with leather; at others by wedging it on both sides with wooden knees, and fixing cross-pieces above it. Or he may stand it upright and screw it to the bench, or fit the thin extremity into a block of wood or cement which can be held with a holdfast while the thick end is clamped to the table with a "long dog" [22]. By this manœuvre a quarter-face can be worked at a time. A sharp knife is capable of doing most of the roughing out.

An effective and permanent decoration is to stain the groundwork black with nitrate of silver, brown with chloride of gold, or yellow with nitric acid. Horn may be made as plastic as putty by boiling it with quicklime, in which state it can be moulded into any shape, regaining its temper on being subjected to a continuous stream of cold water.

Methods by which New Varieties are Obtained. Grafting. Budding. Layering. Germination of Seeds, and Seed-testing.

PROPAGATION OF FRUIT-TREES

ANY fruit-grower who applies himself with intelligence and zest to his task will not only want to know the regular routine work, but will take a keen interest also in the more scientific branches of the profession. Knowledge of such subjects as the methods of propagation will prove of much practical value. After painstaking study of such matters he will find, when buying, that he more easily and surely chooses the best trees for his purpose. He can tell how old a tree is, whether it has been carefully started on its career and properly tended during its growth, and thus will be able to get the very best value for his money.

The Ideal Fruit-tree. Before describing the actual operations of propagation, it will be worth while to know what is the ideal fruit-tree to be aimed at. A first-class tree is one with a stocky, strong trunk, good roots, and the union—that is, the place where the bud or graft is united to the stock—completely healed over. Stocky or rather short trees with well-branched heads are always preferable to very tall ones; very slender trees over two years old should be avoided. The bark must be clean and smooth, and, above all things, it must be free from injurious insects or fungous diseases. It must be all this before it has arrived at the proper age for planting, which, in most cases, is two years old.

There are, roughly, about seven methods by which various fruits are propagated: (1) From seeds, (2) by separation, (3) by layering, (4) by runners, (5) by cuttings, (6) by budding, (7) by grafting.

Reproduction from Stocks. In the first place, all fruits can be raised from seeds, but unless it is desired to produce a new variety this method is not adopted, as the seeds of some fruits do not reproduce fruit of the same kind as that of the tree from which they came. For instance, none of the varieties of the apple reproduce the same kind from seed. Thus there has never been more than one true Cox's Orange apple-tree grown from seed; all trees of this variety except the first one—which of necessity did come from seed and could not have come in any other manner—have been grown by inserting into other seedling stocks either buds or scions from this original tree, or from others propagated from it.

Apple-trees, then, and all fruit-trees with very few exceptions, are propagated by budding or grafting—that is, by inserting a bud or scion of the variety desired into another tree or seedling. By *seedling* is meant a small tree raised from a seed. These are technically called *stocks*. These stocks are generally obtained from France or other European countries, where, for reasons such as climate and soil, they are raised much more cheaply and satisfactorily than in England. The chief stocks are known as Crab and Paradise. Of recent years, however, there have come into favour two new stocks imported from America, known as Northern Spy and Majetin, which are supposed to be resistant to the terrible scourge of woolly aphis. These stocks are shown [70] in the nursery ready for being worked—that is to say, they have been planted and have taken hold in the soil, ready for being budded or grafted. It is essential that these stocks should be firmly planted, otherwise the tree will never be a perfect one, but will be stunted from the beginning of its growth.

The selection of stock is an important point to be considered, as the nature of the tree largely depends upon the stock used. This is well illustrated by the two photographs reproduced, which were taken at the same time, the trees being of the same age and variety of apple. The first tree [71] was worked on a Paradise stock, and is consequently low-branching and wide-spreading, and blossoms later than the second tree [72], which was grafted on a Crab stock, and is taller in its habit of growth.

The Objects of Grafting. The process of grafting consists in inserting a cutting, technically called a *scion*, of the variety desired into the stock. There are three reasons for this operation. First, by far the most usual reason is to perpetuate the variety, and practically all stocks for commercial purposes are grafted for this reason. Second, grafting is done to hasten fruiting to test a new variety. Sometimes a propagator wishes to test the value of a new variety that he may have raised from seed without having to wait a number of years, as he would have otherwise to do, before the young trees fruited. In this case, as scions from young trees bear sooner when set in old trees than when set in young trees, an old tree is generally chosen as the stock, and the graft is inserted on the branches close to the trunk, this operation being termed *top grafting* [73]. Third, grafting is for the purpose of producing a radical change of nature of scion or stock. Grafting may correct a poor habit, as in the case of the Winter Nelis pear, which is of a weak and straggling habit; it will often modify the season of ripening. This is brought about by different habits of maturity of growth in the stock and scion. A case in point is that of the Twenty Ounce apple, which has been known to ripen in advance of its season by being worked on a variety known as Early Harvest. It is said that the Roxbury russet, when grafted on the Golden Sweet, has been modified both in flavour and keeping qualities. Sometimes, too, it increases the size of fruit, as in the case of certain pears, which, when grown upon the quince stock, will bear larger fruit than on standard trees, quince stock being of a dwarf nature.

Time for Grafting. Grafting is carried out as the sap begins to rise in the trees and the buds to swell. In normal seasons this is, for plums and cherries, the first fortnight in April, and for pears and apples the last fortnight in the same month, though it naturally depends somewhat upon the season.

Choice of Scions. The first thing to do is to select the scions. These are always taken from new wood—that is, ripe wood which has grown the previous summer. They should be about four inches long, with a smooth, clean cut, and there must always be a perfect union between the scion

and the inner bark of the stock. The work should be done rapidly, so that the cut surfaces may not be exposed to the air more than is necessary, and, after the graft has been inserted, all cut parts should be made impervious to air and water.

Methods of Grafting. There are several methods of grafting, the chief of which are the whip graft, the double whip graft, splice grafting, and cleft grafting. The illustrations clearly show the difference in appearance of scions prepared according to the varying methods [**78-84**].

For nursery work that most generally in use is the *whip graft*, sometimes called tongue grafting. For a whip graft both the scion and the stock are cut across diagonally [**80-81**]. The cut surface extends one or two inches, according to the size of the part. A vertical cleft is then made in both, and the two are joined together by inserting the tongue of the scion into the cleft made in the stock. A *double whip graft* is made with two of these tongues in the scion and two slits in the stock. After the scion has been inserted it is tied round firmly with bast, and the whole is then waxed over with grafting wax [**82-84**].

Another form of grafting often used is the *cleft graft*. This is invariably used for top grafting and for regrafting old trees. The stock is cut off horizontally, and split down the centre some two or three inches. Into this is inserted a scion, cut in the shape of a wedge [**79**]. It is usual in the case of re-working old trees to insert two scions into each branch that has been cut, one into each side, as illustrated [**78**], binding and waxing as in the case of the whip graft.

70. STOCKS PLANTED IN A NURSERY READY TO BE WORKED

Splice grafting is the simplest form of grafting that is known. It is seldom used, however, except in cases where the wood is soft and tender and cannot easily be split. The stock and the scion are simply cut across diagonally, laid together, and bound round and waxed.

Scions should be used as soon after cutting as possible, but if they have to be kept it is best to put them in moist sawdust and cover them with sacking. It has been mentioned that in cleft grafting two scions are generally inserted, but if both grow, one is afterwards cut away. In re-working old trees it is advisable not to cut all the branches of the trees away at once, for by so doing the tree will be liable to receive too great a check. Some fruit-growers only cut away the branches that are actually to be grafted.

Attention After Grafting. All suckers that come out near the grafts during the summer should be removed, so that all the nutriment in the tree may go to the scions themselves. Careful watching is necessary, lest the buds should grow with too great vigour, and thereby get broken off by the wind. If there is any fear of this it would be well to pinch off the ends before any injury occurs to the scions, as, if these are once broken out of the tree, all the previous work will have been wasted.

Grafting-wax Formulæ. The following formula for grafting-wax is recommended by Luther Burbank: 1 lb. tallow, 1 lb. beeswax, 4 lb. resin. Some nurserymen prefer a wax with alcohol, which makes it more plastic. They use: 1 lb. tallow, 2 lb. beeswax, 4 lb. resin, and 2 oz. alcohol.

In making the wax, melt the beeswax, resin, and tallow. Allow the mixture to become slightly cool. Turn it out into cold water and knead it or draw it until it is tough and plastic. If the weather is cold when the wax is to be used add more tallow, but if the weather is hot more resin is desirable. If tallow is difficult to obtain, one fourth the quantity of linseed oil will answer as well.

Budding. Budding is the name given to the process of applying a single bud bearing little or no wood to the surface of the growing wood of the stock. It is performed during the month of August, when the stocks have arrived at maturity. If there is any doubt as to the trees having matured sufficiently they may be tested by peeling a little piece of the bark; if it peels off quite easily they are ready, but if it does not the operation must be postponed.

The most convenient size of stock for this purpose is one about $\frac{3}{8}$ in. in diameter. The buds used should be taken from vigorous fruiting trees that produce the type of fruit desired, and from strong, hardened shoots of the season's growth. They are obtained by cutting from an existing fruit-tree lengths of new wood, which are called *budding sticks* [**85**]. The leaves are removed, with the exception of a small part of the stalk of each leaf, which serves as a handle for using the bud, and also acts in some measure as a protection to the bud itself. The bud sticks should be kept in a moist cloth, or, better still, in a small bucket containing water.

It is the practice to remove all small twigs or leaves that may be growing on the stock for 5 or 6 in. above the level of the ground. An opening is made in the bark of the stock, which is technically spoken of as the *matrix*. This opening is made by two slight incisions, one vertical and one transverse, the outer bark only being cut. The transverse is usually the first cut that is made; the vertical cut is then made by inserting the blade about $\frac{3}{4}$ in. lower, and drawing it upwards to the cut already made [**86-87**].

Special knives are made for the work, with a thin, sharp steel blade rounded at the tip, and having an ivory or bone handle, the end of which has been bevelled off like a paper-knife. The bud is then prepared. It is taken from the bud stick, usually about $\frac{3}{4}$ to 1 in. in length being cut, as shown in the illustration [**91**]. All the wood from the back inside the bark is trimmed or gouged out [**92**]. The ivory end of the knife is used for slipping in the matrix and loosening the bark on each side of the vertical cut, so that the bud can be placed in without difficulty. The bark is then pressed home again over the bud that has been inserted, and the whole tied round

firmly with raffia [88-90]. In two or three weeks, if the raffia appears to be cutting into the swelling buds, it should be severed.

No further attention need be paid to the buds until the following spring, when in the case of those that have taken successfully [93-94] the stock is cut off immediately above where the bud was inserted. In the case of any that have not taken, the stock may be grafted.

Pruning Young Trees in the Nursery. It has been mentioned that the best trees to select are those that are stocky. Anything which tends to assist the health of the trees and to make them grow with vigour will aid in this direction. One of the first essentials is that they should have plenty of room. For this reason the rows in the nursery should be from 3 to 4 ft. apart, and the trees themselves a foot apart in the rows. The rubbing off of the leaves should not be carried out the first year, as this would cause the trees to grow too much at the top, making them tall and slender, and what is termed "leggy." With some fruits, however, such as sour cherries, the trees may be inclined to break out into strong side-branches, and these should be removed.

Young, healthy budded stock should reach to a height of at least 4 ft. in the first year. The nurseryman now has to decide what form of tree he wishes to grow, and to head back his tree accordingly to 3 or 4 ft. Should any suckers spring out below the union, the earth must be carefully scraped away and such suckers cut off close to the stock.

It is always advisable to drive bamboo canes into the ground against each young tree, and carefully to tie the young trees to supports, so that they will not be blown over by the wind or broken off by careless workmen who may be working in the nursery. This will also ensure them being trained straight, making better trees in consequence.

Cuttings and Layering. Practically all bush fruits, such as gooseberries and currants, are propagated by cuttings. Some, such as loganberries, are propagated by layering. There is no general rule as to the length of cuttings, but they usually bear from six to ten buds. They are taken in autumn from well-ripened new wood of the season's growth. They are then planted in rows on well-prepared soil, the rows being about a foot apart, and the cuttings about 2 in. apart in the rows. About a third of the cutting is placed in the soil, and care should be taken to give a slanting cut just below the bottom bud, as it is from the buds that the roots will form.

The method of layering loganberries is to bend the tips over and bury them in the soil without severing them from the parent plant. The tip strikes root; the new plants are severed when they have taken firm hold—that is, when they have begun to strike roots—and in the autumn are transplanted into the position that they are to occupy. If more convenient, they may be planted in a piece of ground where they may be kept for a year, and removed to their permanent place and wired in the second year. Blackberries are treated in the same manner.

Black currants and gooseberries are sometimes propagated by layering in the following way: outside shoots are bent down to the ground, and at one or more points covered over with soil about 3 in. deep. From each covered portion shoots will form, and a young plant is obtained by separation of these young plants so formed.

Raspberries throw out suckers or young canes direct from their roots. It has already been mentioned in the chapter on Pruning that raspberries bear on these young canes in the following year. Frequently, however, they make more canes than are needed for fruit-bearing—in other words, they produce more canes than the roots are able to supply with sufficient nourishment to produce fruit of economic value the following year, and also some in the centre between the rows where they are not required. These surplus canes can be dug up and transplanted, this being the means used for propagating raspberries.

Propagation of Strawberries. The propagation of the strawberry is quite different from that of any of the other fruits. The strawberry has the peculiar habit of throwing out a long, straight stem with joints at intervals. These stems lie on the ground and take root at the joints, and a young plant forms at these points. It was mentioned when dealing with the cultivation of the strawberry that these runners are cut off as soon as the fruit is picked, so as not to take the vitality from the parent plants, but if new plants are required for a new plantation some of these runners must be left. A single runner will produce as many as three or four young plants, but care should be taken to head them in, and to allow only one plant to form on each runner. This is done by cutting the runners off beyond the first plant. It is not advisable to attempt to propagate young plants unless the ground is somewhat moist, so that the young plants can obtain a foothold, because they have to strike root of their own accord without any soil being thrown over them as in the case of layering. These young plants should be strong enough for setting out in the September or October of the same year in which they spring from the parent plant. If, however, they are to be planted in a loose soil where the frost might cause them to be lifted out of the ground, it is advisable to leave transplanting them until the spring.

Creating New Varieties. Up to this point this chapter has given in brief outline the method of propagating fruits and the treatment they require in the nursery, which it is to be hoped will be of practical assistance to any who are ambitious enough to raise their own trees, bushes, and plants. We now pass on to deal with the discovery of new varieties, a much more scientific process, which

will be looked upon by the grower more as a hobby, because it takes a considerable amount of time and patience to meet with any success. Of the nurseryman's business, however, it forms a very important part. The enterprising nurseryman has always in his mind the possibility of adding to the varieties of fruit already in existence. With this end in view he tries to improve existing varieties which he possesses, to arrive at new varieties of special value, and also to raise entirely new fruits.

The account of this work may be divided into two headings—breeding and selection. The former consists in taking two different varieties or fruits and from them evolving a third, as, for instance, in the case of the loganberry, which is the result of a cross between the blackberry and the raspberry. It will readily be appreciated that a great many factors have to be considered in this important work, such as hereditary influences, environment, the chief characteristics of the two fruits that are being united in respect of such matters as texture, flavour, colour, sweetness, and season of ripening; likewise the stock of the parent trees.

The actual process of breeding consists in extracting the pollen from the blossom of the one and depositing it upon the stigma of the other variety. This operation is termed pollination, and results in the blossom so treated being fertilised. This having been accomplished, Nature does her part.

It may be well to draw attention here to a fact that is not generally appreciated—namely, that, botanically speaking, the real fruit or seed is very often not what is eaten, but what is thrown away, as, for instance, in the case of the plum, it is not the pulp but the kernel inside the stone that is the true fruit—that is, it is that part which is the germ of new life. This is the case with the plum and also with the apple, while with the walnut and chestnut the outside is thrown away, and the part that is eaten is the seed from which the new life is to spring. This seed, whether it be the kernel of the plum or cherry, the pip of the apple, or the seed on the surface of the raspberry or strawberry, or the actual fruit of the chestnut, has to be sown, and the seedling raised gives us the new variety.

Selection. Selection is the practice of choosing the best, and is what might be termed a partner to breeding, the one being supplementary to the other. One of the greatest of plant-breeders of modern times is Luther Burbank, who has done most of his work in California, and has been termed the "Plant Wizard." He has not only improved domestic fruits, particularly plums, but has extended his work to flowers as well, and, what is far more important economically, has altered the character of the cactus plant.

The high economic value of this can hardly be recognised in this country. There are thousands of acres of dry, barren country in America on which nothing will grow with the exception of different forms of cactus, a plant that has caused thousands of pounds' worth of damage by lacerating the legs and sides of horses and cattle, not to mention the clothes of men who have had to travel across or live in the sandy desert plains. The cactus has now been so improved by breeding that a variety has been obtained with neither spines nor thorns, and edible for man and beast. This only shows what can be accomplished, and the endless field there is still lying untouched for the student of research.

Among other creations of this expert are the primus berry, which is a union of the raspberry and blackberry; the plumcot, a union of plum and apricot; a stoneless plum; a walnut with a shell so thin that the birds destroyed the nuts, necessitating a reversion of the process to secure the right thickness of shell; a walnut minus the tannin which gives to the thin, brown skin its unpleasant flavour; a chestnut-tree producing fruit in less than two years from the time of seed.

The amateur will be disappointed if he enters upon the work of breeding lightly, for in some cases the best results are only to be obtained by employing the two methods of crossing and selection. Even then, in the case of plums, a number will have to be employed to combine the characteristics of the fruit that is ultimately desired.

When a bloom has been pollinated it is carefully covered over with muslin, to prevent any other agent, such as bees or insects, interfering. Later the fruit forms, and when thoroughly ripe the seeds or kernels are carefully preserved for sowing. Hundreds of thousands of these seeds must be sown. From these the young trees or plants will grow, and from those most promising scions are taken and grafted, usually on to old trees. Sometimes as many as a dozen varieties are grafted on to the same tree. Old trees are selected for this purpose because the scions will bear earlier than if grafted on young trees or left to bear by themselves. [See page 5064.]

As soon as they bear fruit a careful selection is made of those trees which have most nearly conformed to the ideal that the breeder has had in view. When it is remembered that perhaps only one in ten thousand of the seedlings will be any improvement on existing varieties, and that, as in the case

of plums, it will be four or five years before a fruit may be produced on this young seedling—and its merits cannot be judged until the fruit is produced—it will be readily appreciated that the work requires a great deal of care and patience.

Germination of Seeds. Everything depends upon the seeds and their proper germination. There are three fundamental requisites for the proper germination of seeds: (1) moisture, (2) temperature, (3) free oxygen.

Moisture must be considered the most important factor in the raising of seeds. Different seeds naturally require different amounts of water. This may be due either to the difference in the variety of the seed or because the seeds vary in their power of germination. Weak seeds require more attention and care in respect of moisture than strong, healthy seeds. A good plan is to cover the seeds with moss, which will keep the surface moist longer than if it were exposed direct to the air. It also aids in preventing the seeds from being washed out of the soil. It is always better to use a watering-can than a hose, in order that the watering may be gently done.

Even strong seeds should never be drenched, as that is likely to impair their vitality; the earth should simply be kept damp. The soil should be pressed firmly about the seeds, so as to prevent their drying too rapidly A good plan is to place the pots in which the seeds have been sown in a shady place, covering them with a piece of glass, having first laid a piece of stick across the pot on one side under the glass, thus allowing for ventilation to prevent the soil becoming sour.

Temperature and Germination. Although variations in temperature are not of so much consequence as variations in moisture, it is, nevertheless, very important that extremes should be avoided, and a comparatively uniform temperature should be aimed at. For this reason, as well as to keep them moist, it will be found advisable to keep them in at least partial shade.

It will be readily seen that if the seed pots or boxes are placed in the full glare of the sunshine in the daytime, there will be a great difference in the temperature in the cool of the evening.

A gentle bottom heat will be found to assist, particularly at night, in keeping an even temperature. It is difficult to lay down a fixed rule as regards the temperature required, as this varies according to the seed, but generally a temperature of about 60° F. will be found suitable for hardy fruits.

Free Oxygen and Light. The supply of oxygen usually regulates itself, but care must be taken that the seeds are not sown too deeply, and that the soil is porous, which aids ventilation. Badly ventilated soil will cause the seeds to rot.

Seeds will often germinate in full sunlight, provided care is taken to maintain the right degrees of moisture and temperature. It is well known, however, that some seeds will not germinate, or will only do so imperfectly, if subjected to a strong light. Unless one has made a very careful study as to the likes and dislikes of seeds in this connection, the safest plan is to keep them in at least partial shade. It is often stated that if seeds have once been allowed to become dry after sprouting they will become useless. This is not the case, however. Many seeds will re-germinate several times, and although, naturally, the best results are obtained by the seeds germinating only once, it is well to warn the amateur that his work is not entirely thrown away even if, through some oversight, the seeds have been allowed to become dry.

Seed Testing. It may save time and trouble if the seeds are tested before being actually sown. The simplest method of doing this is to soak hard seeds for a short time, then place them in a thick piece of flannel that has been soaked and laid in a shallow tray or dish, so that the flannel can be kept moist. Place the tray over a gentle heat, such as on the pipes of a cool greenhouse or in a frame. In the case of such seeds as raspberries and strawberries, it will be found that they will begin to sprout in about forty-eight hours. These sprouts are technically known as *chits*—in other words, the appearance of the chit is the first development of the germ of life. As soon as these chits begin to appear, the seeds can be sown, care being taken not to damage the chits.

Sowing. The seeds can be sown either in pots or in shallow seed-boxes, but, as a rule, the best results are obtained by sowing them in pots; particularly is this the case with the seeds of trees.

The soil must have perfect drainage, and this is more easily accomplished by using pots, as pieces of broken pots can be placed in the bottom, allowing the water to drain away. The soil used should consist of a liberal allowance of sharp sand and leaf mould. Good old garden loam, to which an equal quantity of sharp sand has been added, will make one of the best combinations. It is not a bad plan to place some coconut fibre in the soil, as it retains moisture and allows perfect drainage, thus helping to a considerable extent in keeping the soil aerated.

Care against Damping Off. One of the most common ailments of seedlings of this nature is that of *damping* or *rotting off*. The first indication is that the stem becomes brown close to the surface of the soil; it then rots and falls over. Strangely enough, it is a fungus that is the real cause of this; the top may remain alive and even fresh in appearance for several days afterwards. There is more than one fungus that may be answerable. Crowding and careless watering, causing a close and moist atmosphere, are principally responsible. For instance, when only sufficient water is given to keep the surface moist, while the soil underneath remains hard, the seedlings are liable to damp off.

As soon as the seedlings have grown to a height of three or four inches, it is well to transplant them into thumb pots, or even larger. A few months later they may be transplanted into a seed-bed in the open that has been carefully prepared. By the autumn they should have made a growth of from one to two feet, when they may be again transplanted into the nursery rows about 10 ft. apart. Here they may be left until they fruit.

It has already been mentioned that, to test the value of these young seedlings without waiting until they bear fruit themselves, the nurseryman will take buds or scions from them and work them on to trees of older growth, thus causing them to fruit earlier. In the meantime the seedling has been growing into a sturdy tree, so that, by the time that the bud or graft has demonstrated whether the fruit is of any commercial value, the seedling, if it is valuable, will be in a condition to furnish sufficient buds or scions for working a number of trees.

If, however, as is the case with 999 out of 1000, the new fruit is of no value, the work has not been entirely thrown away, as the nurseryman has a supply of stocks that have been carefully reared ready to be worked with a variety of fruit for which there is a demand, and they have afforded him an interesting study and possibly useful experience for his future work.

The Vegetable Basis of Artificial Silk. Chemical Principles of its Manufacture. Viscose Silk. Modern Uses.

ARTIFICIAL SILK

THE idea that silk might be artificially produced was perhaps first suggested to the mind of Réaumur when, in 1743, he conceived the possibility of forcing some of the fluid from the glands of the silkworm through minute orifices, or to the fisherman of some earlier date when he took the gummy fluid of the glands and drew it out for the purpose of producing a gut. In spite of these early observations, the production of silk from the natural fluid has been left to the silkworm's unaided efforts, and it was in quite other directions that chemists eventually succeeded in producing a commercial article in close imitation of the natural product.

Cellulose, a material entirely of vegetable origin, in one or other of its conditions, such as cotton or wood pulp, forms the basis of all artificial silk. This product is entirely different chemically from the material constituting the natural article. There are three independent methods employed in making artificial silk. They are as follows: (1) nitro silk, (2) cuprammonium silk, (3) viscose silk.

Nitro Silk. The discovery that gun-cotton could be got into the condition of a tacky fluid (collodion) by dissolving it in a mixture of ether and alcohol led Andermars, in 1855, to take out a patent for drawing off filaments from this solution. This may be said to be the beginning of the production of artificial silk by the nitro process. This silk was very inflammable. Weston, in 1882, patented the de-nitration of nitro-cellulose by treating the inflammable silk with such reagents as ammonium sulphide, which resulted in a product which is no more inflammable than ordinary cotton, although still containing a small residue of nitrogen. In 1884 Count de Chardonnet succeeded in forcing collodion through small apertures or orifices, and Lehner made certain important advances in its production, particularly in regard to the viscosity and concentration of the spinning solution. The former eventually established large works at Besançon and the latter at Frankfort-on-the-Main. The process as at present conducted is still more generally known as the Lehner-Chardonnet process. Filaments are forced through capillary glass tubes into the air, into an enclosed chamber from which the vapour of ether and alcohol is, as far as possible, recovered. The filament immediately sets to a thread, and is wound on to holders, and rendered non-inflammable by treatment with de-nitrating agents, after which it goes through other operations, when it finally emerges as the finished skein.

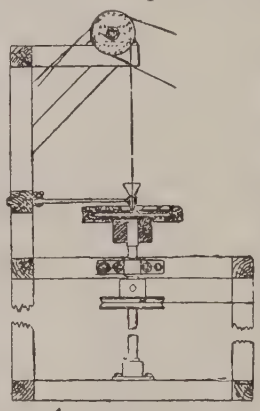
Cuprammonium Silk. The discovery which eventually led to the introduction of the cuprammonium process is generally attributed to Schweitzer, who in 1859 discovered that cellulose is soluble in a basic copper compound, or in copper hydroxide in the presence of ammonia; but the real discovery may be said to date from Mercer's discovery, of an earlier date, that copper nitrate spread on a piece of cotton fabric, if moistened with caustic soda and subsequently with ammonia, produces a reagent which is capable of dissolving the cellulose. Cotton may be dissolved by adding slowly to a little copper sulphate solution a solution of caustic soda until the whole of the copper is *just* precipitated, washing the precipitate on a filter paper, which precipitate, if moistened with strong ammonia, will be seen to change to a deep blue colour and to immediately dissolve the cellulose of the filter paper. This simple experiment is easily tried by the student.

How Artificial Silk is Made. The general modus operandi is to take cotton which has been previously cleansed from impurities by boiling in soda and bleaching, and to add to it a certain proportion of precipitated basic copper salts produced as above described. This mass, after thorough incorporation, is pressed to remove the excess of moisture, in which condition it is known as "blue-cake." It is then put into an enclosed chamber, together with a certain amount of ammonia, water, and other ingredients, and by the aid of mechanical stirring it is reduced to the condition of a viscous blue fluid. This liquid is pumped under pressure to the "pinnerettes." These consist of perforated discs attached to nozzles made to discharge into a coagulating bath. Through the minute holes in the nozzles the threads emerge into the chemical liquid. This liquid, according to the older method, and still largely practised, is sulphuric acid. This immediately converts the lipuid into a number of solid-made microscopic threads of regenerated cellulose, with the simultaneous production of ammonium sulphate and copper sulphate in the coagulating baths. The thread passes on to holders, whence it is washed, bleached, dried, spun, skeined, and finished. The coagulating bath has to be carefully maintained at constant temperature and constant composition. Each nozzle is provided with a sufficient number of holes, usually about sixteen, to form the yarn. The speed at which the thread passes through the coagulating bath is about forty yards a minute. By varying the consistency of the liquid, the size of the orifices, as well as the number of holes and the speed, yarns of different weights, or "counts," can be produced. For preparing the different "counts" (*i.e.*, denier) the number of threads is commonly varied.

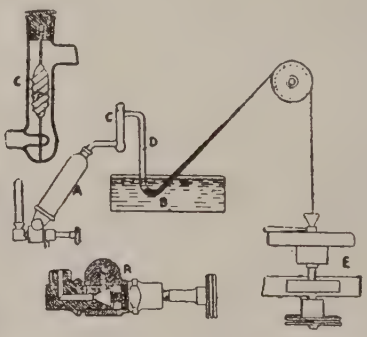
Some Recent Improvements in Manufacture. In 1890 Despessis took out a patent for the manufacture of artificial silk by the cuprammonium process, and this was followed by a large number of patents by Bronnert, Fremmery, Pauly, Urban, Linkmeyer, Friedrich, Dreaper, Tompkins, and others. The artificial silk was originally produced by coagulating in strong acids at low temperatures. It was subsequently discovered that the silk could be produced to better advantage in weaker acid and at a more moderate temperature. Great improvements have resulted in the manufacture of artificial silk by the cuprammonium process in consequence of the introduction of an alkaline precipitating bath consisting of caustic soda with or without the addition

of other salts. In some cases a stronger and more elastic thread results, and the difficulties resulting from the use of a strong acid are avoided. Side by side with these rival processes the cuprammonium process has made great advances during the last few years. As the chemicals used are expensive in comparison with the viscose process about to be described, the completeness of their recovery and their use over again is an important matter. Both the ammonia and the copper are recovered and used again, whereas with the viscose process the resulting by-products have to be disposed of, as they are not capable of recovery. By the cuprammonium process, not only is artificial silk produced, but also a single-thread substance in imitation of horsehair which has formed an important article of commerce in Germany for the manufacture of crinoline for ladies' hats. This product fetches sometimes a higher price than artificial silk. There are difficulties in the way of producing this class of article by the viscose or other process, the cuprammonium process being pre-eminently suited to the production of monofils from fine hairs to thick guts.

Viscose Silk. Mercer's classical discovery that strong caustic soda had a peculiar action upon cotton, causing it to swell up, bringing about the process of mercerisation, is the basis of what is now a very large industry in the shape of mercerised cotton goods. No commercial use seems to have been made of Mercer's discovery for at least twenty years. In 1892 Cross, Bevan, and Beadle discovered that mercerised cotton is capable of being converted into a soluble substance by the addition of carbon bisulphide. Thus, to cotton pulp is added a strong caustic soda solution. The mass swells up to the condition of breadcrumbs. To this is added carbon bisulphide in a closed vessel. The product gradually changes to a yellow buttery mass which, on the addition of water and stirring, dissolves to a clear, treacly liquid. This product is known as *viscose*. For the manufacture of viscose silk this has to be very carefully prepared, filtered, and squirted through fine orifices into a coagulating bath, from which it emerges in the form of a filament, afterwards undergoing various mechanical and chemical processes, after which it forms the viscose silk of commerce. The chief raw material in the manufacture of nitro and cuprammonium silk is cotton, but for viscose silk wood pulp is almost exclusively used.



1. SPINNING BOX



2. VISCOSE SPINNING PLANT

In 1894 Stearn projected a solution of viscose through a small orifice into a precipitating or setting solution, which converted the liquid into a solid filament. Viscose has the peculiar property of being solidified by such substances as brine, sulphate of ammonia, etc., so that if a thin thread of liquid be projected into a bath of such solution it becomes a solid thread.

Improvements were made by Topham for filtering the solution by passing it through various filtering media to deprive it of every particle of dirt or fibre, the plant being so arranged that every particle of air is eliminated [2]. This is absolutely necessary, or the nozzles would otherwise get blocked and the threads broken. The manner of manipulation now is that a number of threads, perhaps twelve at a time, are drawn or forced through a perforated plate, immersed in the setting solution [B 2], then over a pulley, and then are twisted together by an ingenious spinning contrivance [E 2 and 1], where centrifugal force is taken advantage of in giving the filaments a pull and a twist; the thread is laid as an annular mass, which is periodically removed from the box.

In the production of artificial silk absolute control in every respect was found to be essential. Thus, the rate of flow had to be automatically regulated. This was formerly done by a glass valve float fitting a tube [C 2], and floating in the solution and covered on its surface with veins or spiral grooves, through which the solution finds its way. This flow causes the valve to rotate, and, by the position of the float, the supply is automatically controlled, and delivered in a regular stream from the pump to the squirting nozzles. This valve can be set to alter its delivery according to requirements.

Important improvements rapidly followed in all stages, including the preparation of the viscose, dissolving, agitating, stirring, spinning, precipitating, and in the subsequent treatment of steaming, washing, purifying, bleaching, drying, etc.

Care Required in Spinning. It will readily be realised that the diameter of filament is dependent upon the pull or "draft" from the squirting nozzle in relation to the amount of solution passing through the fine orifices, and that this has more to do with the fineness of the thread than the actual diameter of the holes through which it passes. The lustre, feel, elasticity, and physical qualities generally, are affected and controlled by such considerations. But apart from these, and the chemical and physical qualities of the liquid viscose, the processes that follow the first formation of the thread produce profound modifications, such as stretching and drying under tension which are important in their influences.

Viscose Filaments. The filaments are not necessarily circular; in fact, magnified sections show them to be angular, due, no doubt, to their contact one with another while still in a mouldable condition. Exactly the same influences are at work in a state of Nature as with flax and esparto fibres. When a bundle of fibres are pressed evenly together, either by reason of their internal growth and expansion or pressure upon them exerted laterally, the tendency is to the formation of tubes, hexagonal in section. Stearn confined his attention to the problem of rendering viscose a homogeneous product, discovering a suitable precipitant that would enable the spinning to be done at a high speed, and

investigating the physical changes that occurred during the ripening, and to devising mechanical appliances for producing a uniform product.

In the course of development it became manifest that careful preparation of the solution was of paramount importance. This had to be attended to at every stage; and there is as much science and skill needed to accomplish this as is necessary in the brewing industry—perhaps even more so.

Ageing. We have already stated that the viscose solution is undergoing molecular changes from its very inception to the time of its coagulation. For spinning, the solution has to undergo a process of "ageing," and further chemical treatment, and at the right stage it is spun so that the filament becomes coagulated or solidified *while still in a soluble condition*, and is subsequently rendered insoluble. This important advance we owe to Stearn. Viscose silk [3] is now prepared in large quantities. It possesses the most beautiful lustre and excellent qualities for spinning and weaving.

The production at first was slow, but there are now a number of factories producing the artificial product, and artificial silk, by one or other of the well-known processes, is likely to become one of the most important industries of the future. A minute examination of the history of these several processes is perhaps one of the most valuable object lessons to the young aspiring chemist.

A monograph on "Cellulose," by Cross, Bevan, and Beadle (Longmans, 1s.), and later publications, might with advantage be consulted by students who desire a closer acquaintance with the chemistry of the subject.

Difficulties in Manufacture. The difficulties in the successful manufacture of artificial silk are enormous, and it is hard to say which process offers the greater difficulties. Many millions sterling have been spent in different countries in arriving at the best methods and in achieving commercial success. Between laboratory experiments and proper factory routine there is a great and almost insurmountable gulf which has taken the now successful concerns many years of indomitable industry and hard labour to bridge over.

3. SKEIN OF ARTIFICIAL SILK

Among the numerous difficulties may be mentioned the proper choice and preparation of the raw material, which means all the difference between success and failure. Cotton is perhaps the chief raw material at present used, as it serves for both the nitro and cuprammonium processes, but, unless the right kind of cotton and cotton of the right condition be chosen, the final result will be useless. The choice of the material is a matter of extreme difficulty. Wood pulp, the alternate source of supply, also presents similar difficulties. At every stage of the process difficulties arise, making themselves evident in the spinning bath or when the final product comes to be tested. It is necessary to produce skeins of uniform thickness, gloss, colour, strength, and elasticity, and possessing these qualities combined in such a manner as to be of service for the different purposes to which the material is to be put. The dyeing qualities also have to be studied. The dyeing, of course, is almost universally done by the dyers, and not by the manufacturer of the artificial silk, who only carries the process as far as the skeins or spools, which are left either as unbleached or bleached yarns to suit the purchaser's requirements.

It will be seen from the foregoing description that artificial silk, by whatever process it is produced, is forced in the form of a viscous fluid through minute holes or orifices either into some suitable fluid which sets it to a solid thread, as in the case of the cuprammonium and viscose process, or into the air, where the solvent leaves as a vapour, as in the case of collodion or nitro silk. These minute threads have to be produced continually day and night from the beginning to the end of the week, if possible without breaking. There are cases in which each attendant has to look after as many as 80 spinnerettes, which is equivalent to the care of more than 1000 individual microscopic threads, produced at the rate of 40 yards per minute. If no break occurs, there is comparatively little to do, but if the slightest thing goes wrong with the solution, resulting in the breaking of a tiny thread, the operator must put it right at once. Where every care is taken over the preparation of the solution by the observation of minute details, the work goes on with mathematical precision, but a slight error in the preparation of the solution may bring the whole operation to a standstill.

Physical Properties. Artificial silk can be made softer and more brilliant than natural silk, but it possesses less strength, and its strength is impaired by wetting; consequently greater care has to be exercised in the washing. On drying, artificial silk recovers its original strength. The coarseness or fineness of the yarn is measured in "deniers." One denier is equal to the weight of half a decigramme on a skein of 450 metres. The following table gives the relationship between denier and cotton counts. The basis of counts is the same for raw, thrown, and artificial silk.

80	denier	artificial	silk	= 64·50	cotton	counts
100	,,	,,	,,	= 53·16	,,	,,
120	,,	,,	,,	= 44·30	,,	,,
130	,,	,,	,,	= 40·75	,,	,,
140	,,	,,	,,	= 37·80	,,	,,
150	,,	,,	,,	= 35·44	,,	,,
160	,,	,,	,,	= 33·08	,,	,,
170	,,	,,	,,	= 31·25	,,	,,
180	,,	,,	,,	= 29·53	,,	,,
190	,,	,,	,,	= 27·50	,,	,,
200	,,	,,	,,	= 26·58	,,	,,
250	,,	,,	,,	= 21·26	,,	,,

Microscopic Fineness of Threads. An ordinary double skein of artificial silk weighs, say, ½ oz., and has a length of 1000 yards, but as each yarn thread such as the weavers employ consists of, say, 15 individual filaments, the ½ oz. skein will contain a length of 15,000 yards, and the 1 oz. of 30,000 yards, of the microscopic filaments. The pound contains, perhaps, if fine, 400 miles of these

tiny threads. At the present price of artificial silk one can obtain 400 miles for 5s. or 6s.; enough for £15 to £20 to lap once round the world. Artificial silk is perhaps one-third to one-fourth the price of natural silk.

The holes through which the liquid is forced are about $\frac{1}{1000}$ of an inch in diameter, and, as these tiny threads undergo further contraction, they are not more than $\frac{1}{10000}$ of an inch in diameter when finished. Even then they are not so fine as real silk, but are fine enough for commercial purposes, and if finer would not be so useful.

By the Tiele process very fine counts are producible, the individual filaments having a fineness of as little as 1 denier. As the yarns commonly used have about 15 individual threads and go about 150 denier, the ordinary unit filament has about 10 denier. The denier of bave of natural silk is, say, 2 to 3. It will thus be seen that, although the artificial silk normally produced and in demand is not so fine as the natural product, it is quite possible to produce it fine should the market require it, but the finely drawn-out artificial silks appear to suffer in gloss.

Uses of Artificial Silk. A few years ago it was estimated that three-fifths of the production of artificial silk yarns was used in the manufacture of such goods as laces, trimmings, embroideries, ribbons, millinery, and upholstery goods. Some of the silk-weavers, foreseeing the profit that could be made if artificial silk could be used in the manufacture of piece goods, continued their trials quietly, and finally compelled the artificial silk-yarn manufacturers, by their repeated requests, to modify their processes so as to produce thinner grades with a silkier feel. Much is now woven into piece goods and dyed in the piece; the result is most gratifying, and the goods are sold in large quantities.

Artificial silk yarns have met with great success in the manufacture of fabrics in which the warp is of a cheaper material than natural silk and the weft of artificial silk, and also in the manufacture of goods in which is used artificial silk spun jointly with other textiles. In the near future the sale of such fabrics is likely to open up a large and increasing field.

Artificial silk, which has been greatly improved and cheapened both by the cuprammonium and viscose processes, has reached such a state of perfection both in regard to methods employed and quality of material produced that, instead of limiting its use almost exclusively to mixed cloths, upholstery and millinery goods, braids, laces, etc., as heretofore, it is now being gradually employed in making all kinds of fabrics composed wholly of artificial yarns, as is done with natural silk, the production increasing more and more every year.

Substitutes for thrown and spun silks are being increasingly used in the manufacture of neckties, ribbons, tapes, braids, and other small wares. Artificial silk is also used in the manufacture of lace embroideries, etc.; its uses are extending, and for some purposes it is preferred to natural silk.

4. A VIEW SHOWING THE WINDING AND SKEINING OF ARTIFICIAL SILK FROM WOOD PULP IN A LARGE FACTORY ON THE CONTINENT

The following table is intended to give some rough idea of the world's production of artificial silk. This is only an estimate; it is impossible to arrive at anything like the exact figures, as there are no returns available.

—	Total lb.	Nitro-Cellulose	Cupram-monia	Viscose
1904..	3,100,000	—	—	—
1905..	4,400,000	—	—	—
1906..	5,100,000	—	—	—
1907..	6,600,000	—	—	—
1908..	8,800,000	4,400,000	3,300,000	1,100,000
1909..	12,100,000	—	—	—
1910..	12,800,000	4,800,000	4,800,000	2,400,000
1911..	12,800,000	—	—	—
1912..	13,200,000	3,300,000	5,500,000	4,400,000

The total production of the world is now variously estimated at somewhere between 12,000,000 to 20,000,000 lb. per annum.

CLAYTON BEADLE AND H. P. STEVENS

A Dictionary of Special Terms and Phrases used in Chemistry appears at the end of the Self-Educator

Time-tables. Passenger Train Staffs. The Passenger Train. Comfort and Luxury. Train Lighting. Salvage Appliances. Rail Motor-cars. Tickets and Fares.

PASSENGER TRAFFIC

THE superintendent of the line, or general superintendent in the case of those companies which have divided the operating from the commercial side, is responsible for the preparation of the time-tables, both public and working. A public time-table, which refers only to the working of the passenger traffic, is issued twice or thrice a year—the summer train service, for the months of July, August, and September, and the winter train service, which remains in force from October 1 to June 30 following, though a few companies issue a third time-table for the months of May and June. It will be easily understood that there is a greater volume of passenger traffic in summer, and a greater volume of goods and mineral traffic in winter.

Time-table Work. A working time-table, which forms the real key to the working of the traffic, deals not only with the arrival and departure times of passenger trains at stations, but also fixes, for the guidance of the staff, their passing times at junctions and stations where they do not stop. In addition, it gives the working of all goods, mineral, special, and empty trains and light engines; in short, every movement of traffic which takes place outside station limits. Can it, therefore, be wondered that a working time-table should be a ponderous volume, which, as a rule, has to be issued in parts for the different sections of the system? The "heavy" lines publish a fresh working time-table each month; and every week, or sometimes every day, supplement it with addenda relating to the altered working necessitated by special trains, duplication of ordinary trains, and the exigencies of the engineering department.

Some companies make use of diagrams, which are prepared for each section of the line, showing how the engine working is arranged, the time and speed of running, and the intersection of the trains where goods and slow passenger trains have to shunt for the express trains to pass them. The London and North-Western diagrams are drawn to scale, with perpendicular lines dividing the day of twenty-four hours into periods of hours, half hours, quarters of hours, and of five minutes; and with horizontal lines dividing the railway into sections of miles-chains, while slanting lines are inked in to represent the traffic timed to run over the line. Thus, the diagram offers a visible picture of the state of the line, whether it is occupied or otherwise, between any two points at any minute of the day; and with this type of diagram any abnormal speed of a train, wait at stations, length of day for the men, or idle time of engines can readily be detected.

Time-table Conferences. Before a time-table is materially revised, time-table conferences—usually summer and winter—are held, which meetings are attended by all the divisional superintendents, together with representatives of the locomotive department, and presided over by the superintendent of the line. Prior to the holding of a conference, suggestions for new trains or altered workings have reached the office from all parts of the system, and such suggestions which are invited must be accompanied by particulars, specifying reasons, likely advantages, and the total increase or decrease of engine and train mileage which each change would involve. The conference thoroughly threshes out these proposals, approving of some and rejecting others. Approved suggestions go to the general manager and traffic committee for ratification, after which the time-bill clerks attached to each divisional superintendent meet and work up the details, filling in the junctions and passing times.

Rectifying Slack Train Working. It would be manifestly a herculean task to arrange the working of trains on a great railway from the very beginning without some previous knowledge of requirements and possibilities, but as traffic develops gradually the work is very much simplified. Of course, the superintendent of the line has to arrange his time-table in unison with that of a friendly foreign company, and at the same time to keep a watchful eye on the doings of competing lines, so as to be prepared to counter accelerations or new trains which might steal traffic from his own company. In arranging for a new train, the first difficulty is to get the others out of the way, and having put in the trunk, so to speak, the second difficulty is to feed and run off it by means of local trains, connections at junctions, and rail and road motor-cars. "Train-runners," or travelling inspectors, are attached to the office of the superintendent of the line. If from the reports that come into the office, either officially or privately, there be reason to suspect any slackness in the working of a train—if a train consistently loses time, or a locomotive be thought not to be doing proper work—a runner is despatched to travel by that train in order to locate and report upon the mischief. Similarly, goods-train runners are sent out to various places to see how the working of the goods traffic can be improved.

Porters, Ticket-collectors, and Conductors. The various grades of the staff associated with the working of the passenger traffic must now be explained.

Porters are divided into platform porters, earning 15s. to 19s. per week; luggage-labelling porters, with 18s. to 23s. per week; luggage-stowing porters, cloak-room porters, and parcel-post porters, earning 16s. to 18s. per week, the peculiar duties of each being explained by their designation, with the exception, perhaps, of the luggage-stowing class. These latter, who are only found at the great terminal stations, are responsible for stowing passengers' luggage in the vans where it can be most easily handled during the journey. For example, the guard must not find his Exeter luggage buried beneath the Plymouth. Platform porters meeting trains are enjoined to attend to the compartments opposite to them, irrespective of class. The duties of ticket inspectors (35s. to 47s. per week) and ticket collectors (28s. to 35s. per week) are to examine and collect tickets, together with excess fares. The best men are selected to become travelling inspectors in corridor trains, where they are generally expected to act as con-

ductors or attendants as well, while in some cases they fulfil the duties of junior guards, but without the pay of that rank.

The increase of corridor trains is, in fact, bringing into existence a distinct conductor class, which must not be confused with that of dining or sleeping car attendants, and which is not necessarily recruited from the ticket collectors. Thus, the Great Northern Railway furnishes "lavatory attendants" on its "crack" trains, and the Great Western Railway inaugurated the practice of having male and female attendants to accompany its Cornish expresses. The Great Western male attendants do more than attend to the lavatories; their services are available for valeting a passenger, while the female attendants, who wear a kind of nurse's unform, will chaperone ladies travelling unescorted, and look after children while their guardians are at meals in the restaurant-car.

Shunters. Very few shunters are employed in the passenger traffic department, as almost all shunting of passenger vehicles is performed by engines, while the movements demanded of this kind of rolling stock are comparatively few and far between. In the working of the goods traffic, however, a large army of shunters is required, and the duties of the men are far harder and call for greater intelligence than in the passenger service. Passenger shunters are practically confined to the sheds where the trains are marshalled. The grades of shunters are as follow: superior foreman shunter, foreman shunter (earning 25s. to 38s. per week), shunter, and assistant shunter (wages 18s. to 32s. per week).

Guards. Just as the passenger train takes precedence of the goods, so the passenger guard [53], as a rule, takes precedence of the goods guard, although not a few among the latter are the better off in respect of pay. A guard is responsible for the proper equipment of his train before starting, the safety and comfort of the passengers during the journey, and must, after the foregoing, give his next attention to the luggage, parcels, despatches, and other packets entrusted to him. Mail-bags are usually accompanied by postal officials; when they are not, the guard is responsible for their safety. It is not generally known that railway companies send their own voluminous correspondence, as far as is practicable, by rail direct, instead of through the post; hence the guards of the night expresses are also called upon to act as sorters to a certain extent.

Duties of Guards. On joining his train, every passenger guard must have with him his watch, whistle, and carriage-key, and take in his van a red and a green flag, not less than twelve detonators, and a hand signal lamp, which must be lighted when passing through long tunnels, and after sunset and in foggy weather. In the event of a breakdown the rear guard must protect the train, by going back for a prescribed distance and placing detonators on the line.

During the journey a guard has a good deal of clerical work to perform. Every parcel is accompanied by a way-bill, which has to be checked, and any irregularity notified. Then, a guard has to keep a journal or "log" of his train, which furnishes a most important record as to proper time being kept, and illustrates a variety of other features concerned with the smooth and economical working of the traffic. In his journal he records the actual time of arrival at and departure from every stopping station; the number of minutes late away from a station; the time lost, and whether due to station, engine, or signals; if signals, whether they were ordinary or engineering signal checks; the number of carriages, carriage-trucks, horse-boxes, and vans taken on and put off; the number of wheels on leaving station where load is altered; remarks as to detentions at stations and in running; general remarks, occurrences to trains, causes of delay, and suggestions for improvement of working; state of weather during journey, if wet, wind, frost, fog, or snow, and between what points; particulars as to whether train was full or empty in each class of compartment; the numbers of the engines employed, and the names of the enginemen and the names of the junior guards. The journal of every through train is sent to the superintendent of the line or running superintendent, and that of every local train to the proper divisional superintendent. The journals of the previous day are carefully scrutinised every morning; and if the examiner find any delay or occurrence which is not, in his opinion, properly accounted for, he wires the divisional superintendent in whose division it happened for a full explanation.

Salvage Appliances. After the Hawes Junction collision, in 1910, the Board of Trade recommended that fire extincteurs and various tools for rescue purposes should be carried on express trains. The companies hastened to supply these, and they are usually stored in cupboards in the guards' vans. When an accident occurs, the guards are responsible for opening the cupboards and handing the tools and other appliances to the train attendants and passengers. The Aisgill disaster, in 1913, pointed to the need of adding a box of surgical dressings to the appliances, and supplying more powerful tools for extricating passengers from wreckage. It also led to the Board of Trade recommending the same, and that the companies should instruct their guards and attendants more thoroughly in general principles of salvage work, and impress upon them that, in an accident of this description, it is of first importance to arrange for someone to watch for any outbreak of fire, and make preparations to fight it.

Grades of Guards. The grades of passenger guards are according to the different ratings of trains, which classification usually comprises: (1) through or express trains; (2) main-line stopping trains; (3) local trains. Some companies, or combination of companies, like those working a through Anglo-Scottish service, have a superior grade of guards, who accompany a train, say, from London to Aberdeen. These men wear a more elaborate uniform, and are dignified with the title of "conductor."

Wages and Promotion of Guards. The wages of passenger guards are from 23s. to 40s. per week; relief guards are paid 27s., pilot guards 25s., and porter guards 20s. It may be noted that a guard of a long-distance through train is seldom as well off as his wages of 40s. per week would imply, inasmuch as some companies give these men no lodging allowance, and they have therefore to maintain what are practically two homes, one at each end of the line. Some companies, again, provide barracks for guards making long journeys. As a rule, a man is promoted straight to guard, and appointed to the charge of one of the least important local trains. But one or two companies have an intermediate grade in the shape of passenger brakesmen, who assist in local workings as required. During the holiday season, the services

of goods guards, with whom it is the slack time of the year, are requisitioned to staff excursion trains. Two or more guards are carried only on trains which are heavily loaded with passengers, luggage, or parcels. The length or intrinsic importance of the train does not affect the question. The business man's city train invariably requires two guards, as one guard would not suffice to ensure smart working. Then, a train may start with only one guard, and pick up another farther down the line. Where two guards are carried, with some companies it is a rule that the head guard occupies the rear van, and the junior guard the front, while with others it is just the opposite, as it is considered that the head guard should be in the van next to the engine. Some companies require all parcels to be placed in the front van, and luggage and mails in the rear; others, again, order it all to be equally divided, as far as possible, throughout the train.

Slip Coaches. "Slip" guards have to undergo special training, and their duties, which call for the exercise of considerable judgment and discretion, can be explained only by describing the practice of *slipping* itself—that is, attaching a carriage to an express train in such a manner that it can be detached at a station while the rest of the train, termed the "main train," passes on without stopping. The advantages of the system are obvious. It allows of "express" journeys to many places which are not of sufficient importance to warrant the stopping of an express train. "Slip" coaches are nearly as old as the railways themselves. One of the earliest lines—namely, the London and Greenwich—was worked in the "down" direction solely on the "slip" coach principle. The main train did not stop till it reached the terminus; meantime a carriage was "slipped" at every intermediate station.

So long as trains were controlled by hand brakes in the guard's van and on the engine, the slipping of coaches required no more complex apparatus than a special form of coupling. However, the adoption of automatic continuous brakes has compelled the use of additional apparatus, whereby the brake hose can be disconnected without impairing the efficiency of the brake power in either the main train or "slip" portion. There are two kinds of automatic continuous brake in use by British railways—the vacuum and the air. Consequently the method of slipping with each differs somewhat. However, we will describe the process as carried out by a railway employing the vacuum brake. A *slip coach* is a composite carriage, with a slip compartment at each end, equipped with a hand brake, a lever operating the slip coupling, a brake indicator, a brake setter valve, and vacuum gauges. The main train is coupled to the "slip" coach by means of a special coupling hook [64], the jaws of which are released by pulling over the aforesaid lever. Underneath the latter is a diaphragm which, while a vacuum exists throughout the train, locks the lever. At the last stopping-place, a slip coupling cock is attached to the brake hose at the point of severance, and its handle is turned to the left, in which position the passage is open for the maintenance of a vacuum throughout the train. The switch of the vacuum brake indicator, contained in a little bracket table, is also turned to the left, so that the indicator displays a shutter inscribed in red letters, "Wrong to slip."

Slipping a Coach. From one to three miles away from the slipping point, the "slip" guard leans out of his end window [66] and pulls a cord which turns the handle of the "slip" coupling cock parallel with the hose. He next turns the switch of the vacuum indicator in the same direction. The result of these two operations is that the "slip" portion now forms a separate and self-contained unit. The vacuum brake, as controlled from the engine, ends with the tail coach of the main train, while the slip portion has retained a residuum. Still the slip coupling cannot be released, as there is a third vacuum holding down the diaphragm. Just before reaching the slipping point, which must be judged to a nicety, the guard lifts the handle of the brake setter valve; a sharp hiss, and the vacuum locking the diaphragm is destroyed, while, at the same time, the indicator displays a fresh shutter, inscribed in white letters, "Right to slip." Then, at the right place, the slip guard pulls over the lever, whereupon the jaws of the coupling hook open, the brake hose parts at the joints, and the train runs in two portions, as shown in 52.

With the London and North-Western Railway all the operations of "slipping" are accomplished more simply by means of a pneumatic apparatus. The rear guard of the main train and the "slip" guard exchange signals, with green flags or lamps, to indicate that the "slip" has been satisfactorily effected. The momentum of the "slip" portion is checked with the hand brake, for the power stored in the power brake is reserved for use in case of emergency. The Board of Trade regulations prohibit "slipping" in a fog, and the companies' rules enjoin the "slip" guard to see that the "distant" signal is "off" before he slips. At night a "slip" portion carries a head-light and also special tail-lamps to distinguish it from those of the main train.

Responsibilities of the Stationmaster. Stationmasters are answerable for the security and protection of the office and buildings and of the company's property there. They are responsible for the general working of the station, the control of the staff, and the economical use of stores. They must take care that waiting-rooms, offices, platforms, and name-plates are kept neat and clean, and must also see that copies of the company's by-laws, Carriers Act, list of fares, statutory and other notices are kept properly exhibited. At important stations the stationmaster attends only to the passenger work, and is accountable to the superintendent of the line, while his confrère the goods agent is responsible for the goods working, and comes under the control of the goods manager. There are stations of such little importance that the stationmaster is the only servant employed thereon, and acts as porter, parcel clerk, and signalman as well; nevertheless, he ranks as a third-class stationmaster, and is uniformed accordingly.

Second and third class stationmasters are weekly paid servants (wages 25s. to 47s.), who have risen from lad porters, while first-class stationmasters receive salaries, and, as a rule, are selected from the clerical staff. Lastly, there is a specially high grade of stationmasters in command of the great terminal stations. Some companies make all their stationmasters except the last-named (who are expected to wear frock-coats and top-hats) wear complete uniform. Others, however, confine the wearing of complete uniform to the second and third class grades, first-class men being allowed to don mufti, though they must wear an official cap, while they garb their stationmasters-in-chief in an elaborate uniform. The stationmaster of a London terminus is a very important official, and when a man has risen to this height the chances of his

ultimately attaining one of the plums of the railway service are pretty well assured.

Traffic Inspectors. Broadly speaking, inspectors are divided into chief inspector, divisional inspector, inspector or sub-inspector, assistant or platform inspector.

The chief inspector is the divisional superintendent's right-hand man, for safe traffic-working first, and for appointment and preferment of the staff secondly. With some companies he ranks as head of the weekly paid staff; arranges all the duties of that staff, together with their annual leave, and when the engineering department requires occupation of the line the arrangements are made through him. In any case, the chief inspector is constantly about the line, making suggestions and conveying instructions with the authority of the superintendent of the line or general superintendent behind him. He, too, is among the officials who accompany Royal trains. The next grade of inspector may be either divisional inspector, responsible to the divisional superintendent, or sub-inspector, in charge of a district, earning from 35s. to 47s. per week, and responsible for all detail work under the chief inspector. The assistant or platform inspector (wages 32s. to 50s. per week) is the stationmaster's deputy at every big station. Under the stationmaster he is responsible for the timekeeping, good order, and cleanliness of the station staff, for the prompt despatch of trains, and for the loading and unloading of luggage and parcels.

Train Formation. The stationmasters are responsible for the proper make-up of passenger trains, although they have to delegate their responsibility. Through passenger trains are marshalled in the carriage sidings or sheds attached to the starting place of such trains. A *programme* is prepared showing the fixed formation of every train—that is, the number of coaches, the class of coaches, the number of compartments, the lavatory accommodation, dining or sleeping cars, Post Office or parcels vans, milk-trucks, horse-boxes, and the like; between what points each coach works, what vehicles are to be picked up or taken off on the journey, and what special vehicles are to be run on certain days of the week. But the programme does more than this. It shows how each of the coaches is balanced on the return journey. Only local trains run through intact to their destination and return in similar fashion, whereas through trains soon get split up. Therefore it is necessary to work out how each vehicle returns, and to state the hour when it is due back. Trains must always be formed in the order shown in the programme, in order to determine the places on the platforms where the luggage and parcels are held in readiness.

Before a train leaves the carriage-sheds the gas reservoirs and lavatory tanks must be filled, clean towels and fresh soap placed in the lavatories, tail and side lamps put on, screw couplings, steam-heating pipe, brake hose, and communication cord properly fastened and arranged, and the gas lighted (except in the case of trains electrically lighted) on the by-pass if it is a night journey, and in the case of a day journey also if there are any tunnels.

Communication between Passenger and Guard. By the Board of Trade regulations every train that travels for a distance of 20 miles without stopping must be provided with a means of communication between the passengers and the guard. For many years this took the form of a cord running under the eaves of the carriage, which was wound up at the end of the train upon a drum in the guard's van, and at the other was attached to the handle of a special whistle on the locomotive. The notice ran: "To call the attention of the guard or driver, passengers must pull down the cord. There are cords on both sides of the train, but that on the right-hand side in the direction in which the train is travelling is the one by which alone communication can be made." Imagine, as a writer pointed out, the nervous girl, or even the average, self-possessed male, in the moment of danger, sufficiently collecting his or her thoughts to remember which was the right cord to pull, let alone the difficulty of reaching out to get at it! The southern lines were the first to improve upon the system. They adopted the principle of having two electric wires running through the train, like two sides of a ladder, which are joined together in each compartment by a rung that is broken in the middle. Draw out the bell-pull in any compartment, and the broken rung is instantly mended, the circuit closed, and a bell in the guard's van starts ringing.

Since 1901 the companies that formerly used it have adopted a standard train alarm signal, which consists of a valve, with a small passage that forms a whistle, and a rod passing through the valve to each side of the vehicle, and having a red disc attached to both ends. Near each end of the rod is also attached a lever, to which is connected one or two chains, usually two, which pass along the inside of the carriage immediately over the windows and doors of the compartments. The pulling of either chain by a passenger will be followed by a gentle application of the brake and the whistle being sounded. At the same time the red disc changes from a horizontal to a vertical position, and so indicates to the officials the carriage from which the communication has been made.

Train Working. The cleaning of carriages after a journey, and filling the axle-boxes with oil (for oil-boxes have almost everywhere superseded grease in the case of passenger rolling stock, and are now being fitted to the fast goods trains), devolves upon a cleaning staff, which, as a rule, comes under the locomotive and carriage department. Every passenger carriage at the end of a journey is as thoroughly cleaned, both outside and in, as time will permit—the floors washed, carpets shaken, and cushions dusted. The haphazard methods of cleaning coaching stock which were so long in vogue are now rapidly giving way to a more thorough and systematised plan, by means of which the work of getting rid of the dust which accumulates on the upholstery, floors, and other parts of the vehicle is expeditiously and searchingly performed. The vacuum system of extracting dust is largely employed, and the companies have built extensive covered sidings adapted for dealing with the vehicles in the direction of cleanliness and hygiene.

Before making a journey, all passenger rolling stock is inspected by train examiners, who, if they find any defect which does not affect the safe running of the vehicle, affix a green-coloured "For Repairs" label, while, if the vehicle is found to be so badly injured that it cannot be used, a red "Not to go" label is attached. Another class of examiners are employed in tapping the wheels with long hammers for the purpose of discovering fractures. Train-examiners and wheel-tappers belong to the locomotive and carriage department.

Refinements of Station Working. A few lines must be devoted here to several interesting refinements which have recently been adopted for smoothing the way for passengers. Information bureaus, where the prospective traveller

may obtain gratis all the information he needs, have been opened at the principal termini, together with writing-rooms, bathrooms, and dressing-rooms. Passengers can have letters, telegrams, and messages addressed to them here; and private rooms can be engaged for interviews. Train indicators have long been used to denote the respective platforms from which the different trains depart, and to enumerate the principal places served by the latter, but arrival indicators are a new feature. The latest kind of arrival indicator is electrically operated. It tells the time each train is due, the number of minutes it is late, the names of the principal stations at which it has called, and the number of the platform where it will be berthed.

Train Lighting. Improvements of a revolutionary character in the lighting of trains have come to pass during the last twenty years. Most of us can remember the primitive, vegetable-oil lamp, now happily a thing of the past. This was the earliest method of lighting railway carriages; and although it formed a byword of reproach on account of its feeble illuminating powers and general filthiness, while it entailed the employment of a special staff of lamp-men, a very long period elapsed before anything better was devised. Compressed oil-gas, with incandescent mantles, is now the standard illuminant for railway carriages.

Every railway company has its own oil-gas works, and the gas is conveyed from the works to the sidings, where the carriages are charged, in mains, to which valves and connecting hydrants are attached at suitable places. The storage cylinders, which hold about 100 ft. of gas and are fixed to the under framing of a carriage, are charged from the mains by means of flexible hose. However, gas cannot be consumed under the high pressure in which it is made, but has first to be passed through a regulator, which reduces the 150 lb. pressure to 1 in. of water, and admits gas at the same rate at which it is consumed in the single or duplex flat-flame burners. Each jet can be regulated, or all the jets in a carriage turned off or allowed to burn on the by-pass, by turning a key at the end of the carriage, while each carriage has a pressure gauge to indicate the pressure in the cylinders and the state of the supply. Non-"gassing" stations receive their supplies from travelling gas-tanks.

Electrical Train Lighting. Although oil-gas is the standard method of lighting railway carriages, a large number of trains are lit electrically. There are at least three methods of electric train lighting—namely, (1) lighting entirely by accumulators; (2) lighting by one dynamo for an entire train; (3) lighting by one dynamo fitted to each carriage. The two latter methods entail the employment of accumulators.

The third—namely, that of a separate dynamo and accumulators for each carriage—is the one which has been practically accepted as the standard method. The dynamo for generating the current is suspended from the under framing, and its pulley is driven direct by a belt from the pulley on one of the axles. As the lamps must be supplied at constant pressure, it is necessary to provide means to maintain the voltage of the dynamo constant over a wide range of train speed. This is usually accomplished as follows: after a certain limit has been reached, the dynamo always runs at a uniform speed and produces the same voltage, no matter how much the speed of the train may vary, which result is achieved by a compensating device attached to the dynamo. When the train is travelling very slowly, or is stationary, the lamps are fed from the accumulators alone, which are automatically connected to the dynamo by means of a mechanical governor. The accumulators are divided into two parts, each half acting as a regulator to the other, and, being always in connection with the lamps, the light remains perfectly steady.

Gas versus Electricity. There are many advantages, from the railway working point of view, in gas over electricity. The former illuminant is much less expensive. The maintenance of a gas-lighted corridor bogie carriage works out at about £6 a year, whereas with electric light the cost reaches about £45, as accumulators deteroriate very rapidly, vibration shakes the paste out of the plates, and the system of regulation by means of slipping belts absorbs a great deal of power. Further, at a high train-speed each dynamo will take as much as 8 h.p., so that on a main-line train of twelve coaches there is nearly 100 h.p. subtracted from the locomotive for light. The worst feature with such a system is that this power is absorbed whether the light is on or not. Then, the enormous weight of the equipment is another drawback. Each carriage carries a dynamo and two accumulator batteries, which, together with the automatic change-over switch, weigh more than a ton. Some new and better methods of electric train-lighting are now, however, being evolved. These are systems which avoid the slipping belt, diminish the weight of the equipment to three or four hundredweight, and claim to reduce the cost of maintenance per coach to about £10 a year.

Several terrible railway accidents between 1905 and 1913—in which gas-lighted trains were involved, and gas escaping from the cylinders under the wrecked carriages is believed to have ignited the wreckage—led to an agitation for the rejection of gas in favour of electric lighting. In 1911 the Board of Trade wrote the railway companies severally on the subject of the illumination of railway carriages, pointing out that from the standpoint of safety electricity was materially preferable to gas. The replies received showed that most of the large companies did not contemplate the adoption of electricity as the standard illuminant, and actual figures were afterwards given which showed that a wholesale conversion would absorb something exceeding £7,000,000. The Board of Trade presses still for the adoption of electric light, and it is certain that in course of time gas will be abandoned, the change taking place gradually. That the dangers of gas may be mitigated has been shown by the Midland and other comapnies, which have begun to decrease the diameter of the cylinders and fit them with a valve which prevents the egress of gas beyond a certain rate.

Heating of Carriages. The heating of carriages forms another phase of work associated with the comfort of the travelling public upon which much skill and ingenuity have recently been brought to bear. The rudimentary apparatus that long held the field was the foot-warmer—an oblong tin filled with water through an orifice, which was then hermetically sealed, and the warmer placed in a boiler until the water was heated. Like the vegetable-oil lamp, this cumbersome apparatus necessitated setting aside a special staff of men to fill, heat, and distribute. Eventually it was realised that an efficient, simple, and economical method of heating could only be achieved by mechanical means. Mechanical heating was first introduced into this country from America about the same time as Pullman cars [55, 69] by the Midland and Brighton companies, the system being that of high-pressure

hot-water pipes, fed from a boiler heated by a coke-stove. This method is still employed in a few sleeping-cars, but as it requires the constant attention of an attendant it is unsuitable for an ordinary train.

The "hot air" system, which was a modification of this "stove" system, was then brought into use. In this arrangement the air was driven by means of a fan over tubes placed in the fire-box or smoke-box of the locomotive, or over tubes containing steam at boiler pressure. This method was found unsuitable, air being a bad conductor of heat. The utilisation of the exhaust steam from the locomotive was also tried and found wanting.

The atmospheric or dry-steam storage system is now considered the best means of warming railway trains propelled by steam locomotives, being economical and satisfactory in operation and low in upkeep. The steam is taken direct from the boiler of the locomotive and passed to each carriage of the train by means of a main steam-pipe. From the latter it passes through a branch pipe to a series of storage heaters, one of which is found beneath each seat. A storage heater comprises a wrought-iron boiler tube, closed at both ends, and filled to seven-eighths of its capacity with a strong solution of brine. The steam is thus brought into contact with the interior tubes, whereupon the brine contained in the latter absorbs a part of the heat, which is then gradually given off at a lower temperature than would be the case with any method of direct steam heating at similar pressure.

A regulator affixed to the back or side of the compartment permits of a passenger shutting off the heat or readmitting it as desired. These heaters require no repairs; the strong solution of brine, of course, is proof against freezing, while the special form of steam-pipe coupling between coaches is unfreezable, absolutely steam-tight, and uncouples automatically when any two carriages are drawn apart. In order to obviate the discomfort of entering cold carriages, arrangements are made for heating trains at terminal stations before the engine couples on. A stationary boiler supplies steam to a main running alongside the platform, and this main is temporarily connected to the carriages at one or more points by means of flexible hose.

Electrical Heaters. Lastly, electrical heaters are occasionally met with in dining-saloons. The heaters are compact in form; there is nothing of a combustible nature used in their construction, and a free circulation of air against the heated wires is provided for. The heaters are fed from accumulators, which in turn derive their current from the dynamos, driven by belts attached to the axles.

Sleeping Cars. Although there is in this country of short-distance journeys nothing approaching the same extensive field for its employment as exists in America and on the Continent of Europe, the British sleeping-car is the most comfortable, the best equipped, and also the cheapest in point of the additional fee demanded for its use in the world. At present, sleeping accommodation is limited to first-class passengers, which is the rule almost everywhere, but it would not be surprising if we were soon to find an extension of such facilities to second and third class travel. An improved pattern of corridor sleeping-car has long been the standard on British railways. The car is divided into a number of state-rooms entered from the corridor. These rooms, as a rule, hold one berth—never more than two—some being convertible into one or two bedded compartments. The berths are arranged transversely, which position has been found to yield greater comfort than the longitudinal Upper berths, unpopular and rarely occupied, have quite disappeared. The bed is no shakedown affair, for its furniture comprises mattress, blankets, linen sheets, rugs, pillow, and bolster. Each berth compartment has its own washing-stand and other toilet fittings. The London and North-Western Company's latest sleeping-cars [**54**] are 65 ft. 6 in. in length, and carried on two six-wheeled bogies. They are electrically lighted, steam heated, provided with electric bells, a lavatory at each end, a buffet, from which tea, coffee, and mineral waters are served, and a smoking compartment, while a supply of hot water is among the toilet refinements. Notwithstanding their great weight—namely, 41 tons—they can accommodate only eleven occupants, each of whom, therefore, accounts for some 3½ tons of dead weight. Before 1903 the supplementary fee for all this luxury was but 5s. over and above the ordinary first-class fare. In that year, however, the northern companies raised the fee on the longer journeys to 7s. 6d. When a car arrives at a terminus earlier than 8 a.m., the occupants may remain in it until that hour.

Staffing and Stocking. A service of sleeping-cars is managed by the superintendent of the line, while the carriage department is responsible for preparing the cars for the road, and washing and mending the bed furniture. The stock of bedding kept by the North-Western Company comprises several thousand mattresses, mattress covers, sheets, rugs, pillows, and pillow cases. There are special halls at Willesden [**60**] where the bedding is kept aired and sorted ready for use. Every car is in charge of an attendant or conductor (wages 25s. per week), who attends to the comfort of passengers. He cleans their boots, brushes their clothes, takes charge of their tickets and collects excess fares, so that their rest may not be disturbed; serves them with tea or coffee, which he prepares in his pantry, and regulates the heating and ventilation of the car. The position of sleeping-car attendant is a coveted post, for naturally it carries with it perquisites in the way of tips. Only thoroughly intelligent and cleanly men of unimpeachable character are selected for the work, and, broadly speaking, they are promoted from among the ticket-collectors and head porters. The inmates of a car generally look to the attendant for help and advice concerning their journeys; hence the latter must be well acquainted with the time-table, and able to display an intelligent interest in the travelling affairs of those under his charge. For the benefit of those who are unable to afford the luxury of a "sleeper," pillows and rugs may be hired from the company, as shown in **61**. These articles are trundled about the platform in glass-covered barrows, so as to ensure perfect cleanliness before issue.

The Travelling Restaurant. Dining-cars were given to the world by America. As might be expected, their introduction has been largely responsible for the increased weight of trains. Cars range from 60 ft. to 70 ft. in length, and weigh from 35 tons to 40 tons [**58, 67, 71, 72**]. The small compass within which a host of articles in everyday use is carried on board ship is constantly quoted, but a far more remarkable system of stowage is observed on board a dining-car, where also the risk of breakage is greater. The kitchen [**70**] and pantry take up about a quarter of the length of the car, and from these confined premises a train like the Scotch express is sometimes called upon to serve 200 luncheons, 150 teas, and 200 dinners, all within the space of time of 8½ hours. The early kitchen-cars were equipped with coal-

stoves. These were subsequently superseded by gas-stoves, while the *batterie de cuisine* comprises a gas-grill, ovens, refrigerator, plate-heater, carving table, cupboards, sinks, and separate boilers for washing up and for making tea.

Organisation and Staffing. The dining-car business has now attained such vast proportions that it necessitates the employment of a special organisation and staff. Most companies place the management and catering of the cars under the chief of the hotels and refreshment department, while one at least has a special officer who, although

68. STEAM RAIL MOTOR-CAR ON G.N. RAILWAY, WITH DETACHABLE ENGINE

he draws many of his stores from the hotel department, otherwise works independently of the latter. Under the hotel chief is a salaried officer who acts as maître d'hôtel to the dining-cars. He may be seen inspecting cars before a train starts, to satisfy himself that all is in order. The staff of a car consists of page attendants, second attendants, a head attendant or conductor, a kitchen porter, a carver, and one or two cooks. The staffing of the cars may be described as an Englishman's job. Without exception, the companies refuse to engage foreigners to wait upon passengers, while some give preference to English cooks. Lads are taken as page attendants between the ages of 14 and 15, and if they give satisfaction they are certain to become head attendants in time. Adults are also engaged as attendants, but the choice of such is practically limited to men who have been waiters in the company's refreshment-rooms or footmen or butlers in private families.

The head conductor or attendant is responsible for the provisions, which are invoiced to him, also for all stores, wines, and the like, while the service staff generally is charged with the cleanliness of the cutlery, linen, and plate.

Provisioning. The provisioning of cars is arranged for at terminal and important intermediate stations. Broadly speaking, the food is cooked on the train, but prepared beforehand. Thus, soups and sweets have only to be heated up, whereas fish and joints have to be cooked while the train is travelling at full speed. The Great Central procedure is to have all the food brought aboard direct from the vendors—the fish from the fishmonger, the game from the poulterer, and so forth—and handed over to the dining-car chef direct. At Euston there is an array of culinary offices, under the supervision of a head chef, who draws up all the menus for the day. In one kitchen sweets and soups are being prepared; in a scullery vegetables are being washed; in a larder joints are being cut up and fish prepared; in a stillroom groceries, pickles, cheese, and fruit are being made into parcels; and in a linen-room maids are checking linen home from the wash, and mending it. All the comestibles for each car, together with a separate package containing tablecloths and napkins, are packed in a large hamper, which has just been steam scoured, and despatched to the proper train. Dining-car cooks form a distinct class, which has come into existence during the last fifteen years. A cook who joins without experience is sent for a week or so up and down the line in company with an old hand to learn his business.

At the end of a journey a car is gassed and watered by the carriage department, which is also responsible for cleaning all parts of it except the kitchen and pantry, this latter task being the duty of the car staff. Some companies have very stringent rules relating to the removal of any food left over, the penalty being instant dismissal if so little as the tail of yesterday's sardine be found in a car on the following morning. The washing of the soiled table linen sometimes falls to the carriage department, and sometimes to the hotel department. By aid of the invoice system it is possible to ascertain exactly how each car is paying. Dining-cars are now a profitable enterprise, but they are not run with the idea of making big profits, the management being quite satisfied if they just pay their way. Most companies now serve à la carte refreshments, except during the service of meals.

Refreshment-room Catering. The majority of railway companies have taken over the ownership, management, and catering of all station refreshment-rooms. In doing so they have been actuated not so much by the desire to establish a fresh source of revenue as to study the comfort and convenience of passengers. It was found that private ownership sometimes led to abuses. It goes without saying that the management and staffing of the refreshment-rooms is a large business of itself, but, as it cannot be said to form a part of the railway industry proper, it need not be described. One new and welcome feature may, however, be noted. The spread of restaurant-car facilities, perhaps, has pampered the travelling public. At any rate, the more enterprising companies have come to the conclusion that, in the case of non-restaurant-car trains, it is good business to bring the refreshment counter to the doors of the carriages, and so obviate the necessity of asking persons to leave the train and walk a few yards. The travelling refreshment-stalls inaugurated by the Midland do this [48]. Equipped with boiler, urns, and ice-safe, they perambulate the platform, and serve out tea, coffee, soup, and the like, freshly made.

The Advantage of Rail Motor-cars. The employment of what are called *rail motor-cars* is a very remarkable development that has taken place on British railways since 1903. From the outset the enterprise was attended by marked success, inasmuch as it at once proved its ability to solve easily some of the problems of the traffic manager. At the present time there is scarcely a railway of importance which has not adopted this new type of vehicle, containing its own motive power.

The idea of rail motor-cars is that they furnish better accommodation, and secure more economical results in working the passenger traffic under certain conditions, which may be enumerated as follows: first, in the case of suburban traffic which encounters competition on the part of electric tramways, the rail motor-car enables a railway company to afford facilities for cheap and rapid transit during those periods of the day when the number of passengers to be carried does not warrant the running of heavy engines and long trains, these latter

being reserved to meet the stress of the morning and evening traffic. Secondly, where the rural branch lines are concerned, the rail motor-car can be used to fill a void by giving a more frequent service than it would pay to do by means of ordinary trains. The general manager of a railway company largely employing such cars for this particular purpose states that the cost of running a steam rail motor-car as compared with a train is as 5½d. for the former per train mile, as against 1s. 3d. for an engine, with four coaches, per train-mile. By means of rail motor-cars, therefore, both the railway company and those residing on branch lines benefit, while, as the cars can also be used to stop between stations, at level crossings, and at other places where roads are close to the railways, they give access to districts which formerly laboured under the disadvantage of being situated some distance away from a station. These intermediate stopping places are called "halts," and it is only necessary to furnish them with a low platform and a small waiting-room.

Different Patterns of Cars. It is not possible to describe all the various patterns of cars now in use on the different railways, but the principal points of distinction between various types may be touched upon. From the road automobilist's standpoint, the term "rail motor-car" is, however, somewhat of a misnomer, as it gives him the impression that these cars are operated with an internal-combustion engine, consuming petrol, whereas there are only two or three instances of this kind of engine being adapted to rail motor-car work.

The internal-combustion engine, as a rule, is not sufficiently flexible for railway exigencies. The necessary high acceleration cannot be obtained with it unless it is made impracticably large, while it cannot respond to overload. On the other hand, it requires much less space for the storage of fuel. At present the vehicles are divided into three classes: (1) steam-operated; (2) petrol-electric-operated; (3) petrol operated by means of an internal-combustion engine.

Common Characteristics. A steam-driven rail motor-car combines on one frame an engine and a passenger car of moderate seating capacity, the total length of the vehicle varying between about 55 ft. and 70 ft. The car is carried on two four-wheeled bogies, that at the trailing end being usually a standard passenger-coach bogie, and the other forming a four-wheeled outside-cylindered locomotive of small dimensions. Sometimes the locomotive is complete in itself [**68**] when detached from the car frames, and may, if required, be run separately for shunting purposes, which are almost indispensable in railway working, while in most other cases the engine bogie is detachable [**49**], and the boiler and chimney can pass through an end door, in order that a defective engine can be replaced. The engine can always be operated from either end of the car, by means of a duplication of the stopping and starting apparatus, whistles, vacuum, steam and hand brakes, for the essence of a rail motor-car is that it can be worked as a shuttle—that is, without having to be turned round in order to keep the engine foremost. A special arrangement provides that the vibration from the engine body is not transmitted to the body of the car.

Types of Boilers and Valve Gear. There are several different types of boilers—namely, a smaller pattern of the ordinary locomotive type of boiler, with or without a Belpaire firebox, and carried horizontally; a vertical multitubular boiler, which kind is the most popular; and a novel generator of the vertical type [**50**]—namely, Cochran's patent boiler. This last possesses a minimum of joints and welds, and has no rivets or welded joints in actual contact with the fire. The feature, however, which affords pre-eminence is the facility that is afforded by the boiler design for obviating internal scaling. Scale formation is an important factor in the life of any boiler under all and sundry conditions. Failure by burnt plates or tubes, and consequent early scrapping of boilers, generally arises from inability to get at the interior so as to clean it effectively. The accessibility of all parts of the Cochran boiler for the latter purpose forms its chief claim to consideration. Sometimes the valve gear is worked by ordinary eccentrics, which are fitted on the driving axle instead of on the frame, and which actuate the valves on the top of the cylinders by means of a rocking shaft from ordinary link motion. More often, however, the cylinders are actuated by the Walschaert valve gear. Sufficient water is carried for the service in a tank or tanks placed below the carriage body, and there is also room for a supply of fuel in the motor compartment or elsewhere.

Arrangement of the Carriage. The carriage itself is divided into two or three saloon-like passenger compartments [**62**, **76**], a guard's and luggage compartment, and a driver's compartment at the opposite end to the engine-room, all having free internal communication, while the entrance to the car is sometimes effected by gangways fitted with "lazy tongs" gates. Electrical communication or speaking-tubes are furnished between the driver's and guard's compartments. For convenience in stopping at "halts" at which no platform is provided, there are steps on each side of the car, which can be either covered by hinged flaps when the car draws up at an ordinary platform, or swung back to the width of the ordinary footboard by a lever. With some cars the outward movement of the steps opens a valve in the main vacuum pipe, and so prevents the car from starting till the steps are locked in running position.

Petrol-electric Cars. The North-Eastern Railway employs a few petrol-electric autocars [**51**], in which the generating power is a four-cylinder petrol engine, 80 b.h.p., that drives a dynamo direct, which in turn generates current for four electric motors, one on each axle of the vehicle.

The Great Central Railway is experimenting with a 90 h.p. type of petrol-electric car, the engine of which operates on the four-cycle principle, and has four cylinders. Two motors are employed, driving on the axles of the rear bogie, each rated at 64 h.p. A separate petrol set is used for operating a vacuum brake exhauster, and driving a small generator, which serves for providing electric lighting of the coach. The Great Western has also embarked on petrol-electric rail motor-cars [**57**, **76**], employing a type in which a 40 h.p. engine drives a dynamo, which transmits power to two motors. Notwithstanding the light weight of the vehicle, 14 tons, it accommodates 44 passengers, the weight per passenger, therefore, working out to only 6 cwt. 1 qr., as compared with about 13½ cwt. for the steam rail cars in use on this railway. A great future is predicted for the petrol-electric system, which not only obviates those disadvantages already noted of the purely petrol engine, but dispenses with the gear-box and clutch and attendant complications. Of course, the drive may be made from either end of the car, and one man is sufficient for attending to the engine and for driving, thereby saving the cost of the additional man needed for stoking in a steam-propelled vehicle. The control of the car is what

is known as "dead-man's handle," which renders it necessary for the driver to hold the controller handle continuously; if it should be released, the energy would be cut off from the motors.

Petrol Cars. These have been tried on several lines, but so far without much success. The vehicles are smaller than any of the steam and petrol-electric cars, and are carried on four wheels. Provision is made for two speeds in each direction. Strenuous endeavours are being made to evolve an autocar on this principle suitable for railway purposes. It is realised that there is wide scope for the employment of light, self-propelled vehicles.

"Trailers." The seating capacity of a steam rail motor-coach varies, according to its size, from 50 to 64 passengers. The more powerful cars [57] are capable of hauling a "trailer" coach, and they are also calculated to attain a speed of 30 miles per hour within 30 seconds of starting, while but few cars are designed to run at a higher rate of speed than 45 miles per hour.

Before ending the description of rail motor-coaches, mention must be made of a later development upon the same lines. Several companies have fitted small side-tank engines to work with "trailer" cars as complete units. Engine and coach are never uncoupled while in service, and duplicate gear in the driver's compartment of the coach, at the end farthest from the locomotive, enables the unit to be worked either end foremost.

Management and Staffing. Rail motor-cars are under the control of the chief mechanical engineer, which he exercises through the district locomotive superintendent in precisely the same way as he looks after engines. It is not improbable, however, that as the employment of the cars becomes more extensive, a special department will be called into existence for the purpose of supervising them. A feeling is growing that since rail motor-cars constitute what is an essentially light, rapid, and mobile form of traffic, they require something less ponderously inclined than the brains of the locomotive department to study their needs and devise technical details.

The staffing of the cars is as follows. The steam-propelled vehicles require the services of both a driver and a fireman, as there must be a man in charge of the boiler. Therefore, when a car is running engine-room hindermost, the men part company, the driver being in the motor compartment in front (which, it will be remembered, is equipped with duplicate controlling gear), while the fireman remains behind. Some companies make the fireman act as guard or conductor as well, but the general practice is to employ a third man. The duties of the conductor of a rail motor-car are the same as those of a passenger guard in seeing to the needs of passengers, looking after luggage, and attending to the safety of the "train." In addition, he often issues and collects all tickets, and, when the car stops at a "halt," acts as the stationmaster, porter, etc., of that "halt." The operation of a car fitted with an internal-combustion engine can be entrusted to one man, the driver or motor-man, a fireman being unnecessary. Drivers or motor-men, together with the firemen of rail motor-cars, are drawn from the staff of engine-men. Conductors are selected from men who aspire to become full-fledged passenger guards; in fact, this service is now regarded as a training field for the latter.

Passenger Road Motor Traction. The functions of passenger road motor-cars are, broadly, to act as feeders to the railways, and so to promote travel in every capacity, while, incidentally, they also serve to exploit tourist districts, to form an efficient substitute for light railways, and to render possible a complete service over a new railway route, starting from railhead, pending the completion of the construction of the line.

Practically every railway-owned passenger road motor vehicle is petrol-driven; among the different types of bodies used are: (1) double deck omnibus; (2) single-deck omnibus [63]; (3) observation or char-à-bancs [65]; (4) open waggonette; (5) composite goods, mail, and omnibus. Each type of vehicle has accommodation for a certain amount of passengers' luggage, together with parcels, and many of them also make a speciality of the conveyance of packages containing agricultural produce, so that a service may fulfil an additional purpose in the way of bringing markets nearer to producers, or of opening up to the latter new areas of supply.

Passenger Tickets. Passenger tickets comprise: (1) ordinary tickets, issued for ordinary trains at ordinary fares; (2) blank card tickets, used for light traffic only—that is, where there are few passengers between a pair of stations in a month, and on which the name of the destination station is omitted; (3) tourist and week-end tickets at reduced fares; (4) excursion tickets, printed specially for each excursion; (5) circular tour tickets, which take the form of booklets of coupons; (6) market, fishing, golfing, hunting, etc., tickets at reduced fares; (7) periodical, season, or contract tickets, which are specially printed, and require, as a rule, the holder's signature; (8) officers', soldiers', seamen, and police tickets, at reduced fares, which are kept in books with counterfoils, and which are issued on the production of orders signed by the proper authorities; (9) workmen's tickets at reduced fares, which are available only by trains running at specified hours; (10) pleasure party tickets, which save stamping, say, 150 separate tickets to the members of a school treat; and (11) privilege tickets, issued to the company's servants. Further, tickets for the conveyance of dogs, bicycles, perambulators, or any other articles carried at owner's risk, are issued at the passenger booking-office.

Manufacture of Railway Tickets. Some companies print their own tickets, and others contract for them, while some do both; but in all cases the printing establishment is under the close supervision of the company's accountant, who exercises a constant check on the supplies.

The manufacture of railway tickets as carried out by the London and North-Western Railway at Euston Station may be described as a representative process. The first room entered is where the multicoloured sheets of pasteboard are received from the papermakers, and where the sheets are stored, and passed through machines which cut them up into the little cards with which we are so familiar. The first machine snips off the rough edges, and divides each sheet into a number of longitudinal strips of the required breadth, while the second machine is fed with the strips, and cuts each into so many cards of the correct length. The cards issuing from the latter machine are ready for printing, and are carried by tray-loads into an adjoining—the composing, printing, and counting—room.

Ingenious Automatic Machine. Great ingenuity has been brought to bear in the perfection of ticket-printing machines. The latest patterns may be described as being self-acting in every respect. The blank cards are fed into a hopper on one side, whence they descend and

pass through the machine in an endless stream so long as the supply lasts, one card pushing the other forward. In the body of the machine each card is impressed with its proper consecutive number; has its face printed with the names of the issuing and destination stations, class, fare, etc.; is then turned over so that its reverse side may have imprinted on it a short notice beginning "Issued subject to the company's regulations," after which it is turned face uppermost, preparatory to leaving the machine by another and similar hopper, in which the column of finished cards is pushed upwards. These machines can print from 10,000 to 14,000 tickets per hour. The supply of ink is automatically fed to the rollers; and in the event of a slightly torn or crumpled card being encountered, the machine stops of itself, and declines to continue printing till the offending specimen has been removed. Lastly, the printed tickets are passed through a machine which automatically counts them in batches of 250 at a time, and records the total number which has passed through it. Here, again, the cards are placed in a hopper, and the attendant turns the handle of a dial to the number borne by the first ticket to enter the machine. The machine is then set going, and automatically stops when it has counted out 250 cards into a hopper below. The attendant must see that the dial records exactly that number, and that it tallies with the number of the last ticket, otherwise one or more tickets must have got lost, or duplicates as regards the successive numbering been printed, in which case very careful search has to be made to rectify the error, for a printed ticket is treated as representing its face value in cash. The latest type of counting machine can deal with 20,000 cards per hour.

Number Check on Tickets. The company's audit accountant is the only officer through whom passenger tickets (save, in some cases, season tickets, which are supplied by the general manager) may be obtained by the clerks in charge of the booking-offices.

All tickets are type-numbered consecutively at both ends from 000 to 9999 inclusive (to avoid printing five figures when the limit of 10,000 is reached), and are marked to indicate the "series" to which they belong, ten thousand of each kind, class, and station making a "series." By the Regulation of Railways Act, 1889, Sec. 6, the fare must be written or printed on every *ordinary* ticket. The different colours and distinctive markings assigned to the tickets for various classes and specific purposes are legion, while there is a curious want of uniformity among companies in the colours that distinguish the classes.

Booking Offices. Inside the booking-office, the tickets are kept in rows of "tubes" so called—really two pieces of wood joined by a spring—which tubes are contained in lock-up cases of various sizes. The name of the destination station and fare is written above each tube, and the number of the next to issue is written on a strip of slate below the tube. The system is to place tickets in the tubes with highest numbers at the top, and, when booking passengers, to draw from the bottom, so that, after the departure of a train, by deducting the number written upon the slate from the number on the next to issue, it is readily ascertained how many have been issued by that train. Below the lock-up cases are chests of drawers containing bundles of tickets to replenish the tubes. At large stations the arrangement of the booking-hall is very methodical, the apartment being divided into classes and districts, with a separate window for each, while the case containing tickets most frequently used is placed nearest the window, and the remainder branch out in geographical order.

77. A GREAT CENTRAL EXPRESS ENGINE TAKING UP WATER

Renewing Stock of Tickets. Here, too, the staff comprises not only clerks to issue tickets, but a ticket stockkeeper, a cashier, and a chief booking-clerk, each of whom has his own office within an office. The stockkeeper periodically replenishes from his own stores the drawers below the lock-up cases; and when he finds that a series of one class between a pair of stations is nearing exhaustion he fills in a "Ticket Demand Note," specifying the name of destination station, route, colour, class, description, fare, number of ticket which will be issued last, and the last progressive number of tickets in stock.

This demand note is signed by the chief booking clerk and sent up to the accountant's office, where it is checked and compared with the ticket stock registers. Each issuing station has an account in the stock registers, and the following particulars are inserted in their proper columns: name of each destination station, route, class, description, date of demand, last progressive number of tickets

supplied, and quantity supplied in bundles of 250, and date of last supply.

Booking Clerks. Immediately after the departure of each train, the "train-book" is made up, showing an account of tickets issued, a separate entry being made for each station and class. The "beginning number" is copied from the slate, and the "closing number" from the ticket next to issue, while the number of each blank card ticket issued has to be entered separately. After the train-book has been made up, the old "beginning number" is wiped off the slate, and the old "closing number," now the "beginning number," written up in its place, when the clerk begins booking for those stations again.

At the close of the day a "proof sheet," or daily classification book, is made up, giving an account of every ticket issued, but before attempting to balance the day's takings the number of tickets that has been issued is balanced in a "Taking Out Sheet." At intervals during the day the clerks have been paying in "on account" to the cashier of the booking-office, and on the following morning, between 9 a.m. and 10.30 a.m., the whole of the takings of the day before are paid to the chief cashier in the accountant's office, and there balanced with the daily classification book.

Checking the Receipts. The takings and tickets issued by each individual clerk are made up separately, so that any individual loss or surplus may be located. The foregoing is the procedure followed at the great terminal stations, where on certain days of the year—the eve of a Bank Holiday, for instance—the number of tickets issued runs into tens of thousands, while the cash receipts total thousands of pounds. And the same system applies on a more or less modified scale, according to its importance, at every issuing station on the railway. At ordinary stations, the stationmaster is responsible for the work of the clerks, and at small stations he issues the tickets and makes up the books himself. For the collection of cash receipts and used tickets, the line is divided into districts. Specially constructed safes travel up and down the line between district headquarters by passenger train, and into these receptacles the stationmasters of intermediate stations place their takings in bags, for which the guard of the train signs, while leather cases containing the collected tickets are also delivered into his charge.

At the district headquarters the cash is banked as soon as it is received, while the account-sheets and collected tickets are forwarded every month to the chief audit office. The daily classification books are not sent up to the audit department, but at the end of each month the whole of the beginning numbers are taken off from the tickets themselves, and worked out on the month's issue. This monthly total must balance with the totals of the daily classification books.

The Monthly Audit System. The task of getting out the monthly audit of the receipts from all coaching traffic is very laborious, and necessitates the employment of a special staff of clerks and ticket-sorters, the latter consisting of boys, or sometimes women. Each collected ticket has to be sorted back into its proper series of kind, class, and station, and a note taken of missing numbers and tickets irregularly issued. Directly the monthly audit is completed, the sorted tickets are defaced and destroyed. Schedules of tickets missing are sent every month to the station responsible, for an explanation, and, should the number be unusually large, an investigation is ordered.

Automatic Ticket-printing Machines. The ordinary ticket system has certain disadvantages from the standpoint of the issuing clerks. For example, if a clerk issues in error a ticket out of its numerical order, he has to account for all numbered below it; and it also makes accounting of tickets a long and troublesome business. Attention is now being given to the subject of automatic ticket-*printing* machines (not to be confused with automatic ticket-*issuing* machines), to be operated by the booking-clerks themselves at the stations. These machines obviate the need of storing printed tickets, which takes up a great deal of room, and do away with all the risks of fraud and loss which the old system invites. The Great Western was one of the first companies to employ such machines. The machine in question can print tickets for as many as 2000 destinations. It consists essentially of an octagonal roller, bearing the names of the various stations, and a moving carriage, containing the actual printing apparatus, and rolls of paper for recording the transactions. When asked for a ticket, the clerk inserts a blank card into a slot in the carriage, and then slides the carriage so that the position of a pointer with regard to the roller indicates the destination and class for which the ticket is to be printed. The clerk next moves a lever, and the printed ticket is ejected from the slot. Simultaneously with the printing of the ticket, the transaction is recorded in duplicate on control strips, consecutive number, fare, class, and destination, the latter being indicated by a number, and not by name. One of these strips the clerk can remove from the machine, and paste into the train-book. He is thus relieved of the work of account-ing. The other strip is inaccessible to the clerk but is removed by the auditor in due course.

Training of Booking Clerks. Booking-clerks, as a rule, begin to learn their duties as boy clerks or boy ticket-sorters. Promotion in this branch of the service depends entirely upon intelligence and merit. A smart clerk knows the geography of his line backwards, so to speak, has hundreds of fares in his head, and is a lightning calculator of ticket sums. Another important qualification for a booking-clerk is an unruffled temper. Pertinacious inquirers about subjects which have no concern with the issue of tickets have to be persuaded to move on, and no notice must be taken of the remarks of irritable or ill-conditioned travellers who air grievances against the company on the "man behind the pigeon-hole."

To ease the labours of booking-clerks during the "rush" hours, automatic ticket-issuing machines have been adopted by the Great Western, North London, and Metropolitan Companies.

Ticket Nipping. There is a good deal more in the nipping of tickets by examiners than meets the eye. The practice has a two-fold object—to deface the cards so that they shall not be used over again, and to mark them by impressing a number or punching out a sign or letter, in order to afford evidence of the right of companies to claim a proportion of the through fare when passengers have travelled by a route different from that for which the tickets were issued, or to prove how far a passenger had travelled in the case of a refund claim. A different number or mark is fixed by the Clearing House for each junction or principal station, or group of minor stations, a record of the same being kept there.

Two and Three colour Work. The Forme. Machines. Make-ready. Progressive Proofs. Paper and Inks. Bronze Printing.

COLOUR PRINTING

We have shown in the last chapter how the three-colour copper blocks (yellow, red, and blue) are made from the originals supplied to the process engraver. As, of course, it would be impossible to print very long numbers direct from the original blocks, mainly for the reason that it would take too long and be too expensive a process, we must next show the usual methods for providing the printer with a number of originals. These can be either electrotypes or, as is now adopted in general practice, fine-art stereos made by the Dalziel plaster process [see page 4691]. The actual number of stereos or electros used on a machine is governed by the size of the bed of the machine, and by the size of the job and paper obtainable. The largest sheets usually employed are about quad-crown (30 by 40 in.), this size being more than sufficient to accommodate eight sets of plates giving at view pages 1 and 4 of any of the standard magazine covers, such as "My Magazine." This allows for the necessary margins for the locking-up clips on the machine-beds, and tapes and bands for securing better register by holding sheets close to the cylinder during the actual impression.

Making Up. The *forme*—as the plates on the machine-bed are called—must now be dealt with in detail. The most usual method employed nowadays for making up the electros or stereos into a forme is as follows: an iron bed with grooves into which clips, made up of three parts—the bottom, top, and screw—wedge tightly on a screw, is used, and when tightened up is undoubtedly best from all points of view; it holds plates most securely, yet the register is very easily adjusted, and, furthermore, a bed of this type gives a good, sound impression, and if the clips are in good condition and properly tightened up the plates do not *drive*—shift their position—and detrimentally affect the register. These mounting beds are made in various sizes to suit the different sizes of presses. [See page 5586.]

Colour-printing Machines. Accurate register is essential in good colour-printing, and to get the best results a press should be used for each colour. For the lighter class of two-colour subjects quite good results are obtained by using a two-revolution two-colour press. In these presses both formes are on the one machine, which is provided with a separate cylinder, rollers, and so on, for each colour, the sheet being transferred, after the first impression, by means of a drum and grippers, to the second impression cylinder.

Two-revolution presses are also generally employed for the printing of three-colour letterpress work. This type of press, as stated on page 4822, derives its name from the fact that the cylinder revolves twice to one impression, rising and falling alternately, so that the forme is inked during one revolution, while during the other the sheet is actually being printed, and delivered into the taking-off boards. One of the earliest machines of this type, and perhaps the best known throughout the trade, is the Miehle [see page 4823]. This press originated from the United States, and there are some that have been running in this country day and night for the past sixteen years, and are today still doing good work. For many years past, however, the Miehle has been made in this country, at Broadheath, Manchester.

Other presses very suitable for colour work are the Optimus, sold by Messrs. J. Haddon & Co., and the Huber-Hodgman. As was noted on page 4822, two or three Miehle machines are placed in tandem, and the sheet passes through the machines in succession, the yellow generally being printed first, the blue second, and the red last.

To get the best results from a Miehle, as from any other high-class machine, it must be carefully looked after and thoroughly adjusted at frequent intervals by an experienced man; if this is not done, bad register, which is fatal to good colour-printing, will result. Some of the details which make for the success of this press are as follow: it is easily adjusted throughout, it has microscopical front and side lays, a solid impression, a face-up gripper delivery which prevents smearing, and the forme is readily accessible without disturbing any other part of the press.

For short runs of, say, 1000 or so, it is usual to print from original blocks on any of the up-to-date platen presses.

Dressing the Cylinder. The cast-steel cylinder is *dressed*. Its edges run on bearers on the bed of the machine, which are accurately adjusted to type-high—·918 in.—but the main body has to be covered with packing make-up of glazeboard, linen sheets, manila sheets on which to stick the overlays, and other sheets to suit the particular forme being worked. All these are covered up with a manila, which is fastened tightly, usually being wound round a bar. The formes having being placed on the machines and cylinders dressed, a sheet is printed on each to give the machine-minder an idea as to what amount of underlay is necessary. This, of course, varies according to the subject and the class of paper being used.

Underlaying. An underlay is made from *pulls*, or proofs, of the block, and is used to level up the forme; in some cases, however, it is necessary to reverse this process, and thinning of the plate by scraping has to be resorted to. When dealing with vignetted work, good results can be obtained if the electros or stereos are undercut at the edges of the vignettes, in the same manner as are the original copper blocks.

Underlaying must be done carefully, especially when dealing with light screen-work, as this has always a tendency to work up heavier on the run. The forme having been underlaid, the next procedure is to fit up tapes in margins (as previously mentioned). Then, to secure register, sheets are pulled from the key forme, which is usually blue; and, the furniture and imposition having been passed, plates of the other colours are moved to register with the blue.

Overlays. Register having been obtained, the overlays and making ready are next proceeded with. Overlays cut by hand, when cut by an experienced man, undoubtedly give the best results; quite good results, however, are obtained with the mechanical chalk-relief overlay. This kind of overlay is especially useful when a large

number of sets of one plate are being worked from; furthermore, it is cheaper to produce, especially if there is sufficient work to keep the operator employed all the time. A special coated board is used for these overlays, which is printed on both sides with special ink, on one side direct from the block, on the other by rubber offset process. The card is then etched in a bath of chloride of lime, the solids remaining, and the high-lights and half-tones graduating away according to the amount of ink deposited. Where the ink is solid, the etching fluid will not eat away.

Making Ready. An impression having been made on a tightened-down sheet on the cylinder, the overlays are stuck up to register with this impression. The smallest amount of paste possible should be used, as otherwise lumps will form, and will spoil the result of the overlay. The cylinder is again covered up with several sheets; the quantity used must be sufficient to make up the correct radius of the cylinder. A sheet is now pulled again, to make sure that the overlays have been correctly put up. When all in this direction is right, a further thin sheet is pulled as a guide to the making ready for the letterpress. This is patched up with tissue paper on the back, and any parts that are too heavy cut away. Two further sheets should now be pulled, from which to cut out further thin overlays. These should be stuck on to a making-ready sheet, and the whole put up together in pages. The cylinder having been covered over with a tight sheet, an impression should be pulled on the cylinder, and any final touching up of weak places done thereon. The cylinder must be covered up with the requisite number of sheets, to make up proper circumference, and finally with a tight manila sheet.

Colour Proofs. The making ready having been completed, the colours should be run up and sheets pulled from each press, to make sure that the register is sufficiently correct to enable yellow to start printing.

Progressive proofs—that is, proofs pulled in colour from each of the original blocks—are taken, the yellow being pulled in black as well as yellow, to enable the printer better to judge the strength of block, the red being pulled separately and on top of yellow, the blue separately and on top of red and yellow again. This gives the finished picture. This is the printer's guide, and he must match each colour individually. There are, however, exceptions to this rule in this matter. Progressives are usually pulled on best quality pure white coated art paper, but the paper used for printing the job is usually somewhat inferior, and, what is most important to the printer, it frequently varies in tone from that of the proof. Where this is the case, the printer must depart from the progressive colour-proofs supplied, and use a set of colours that he considers will give him a finished result equal to the proof.

Inks. The usual course adopted with regard to inks is for the printer to submit to his inkmaker a set of progressive proofs and a sheet of the kind of paper that is being used for the job. It is then open to the inkmaker to send in a series of colours that will give a satisfactory result. Inks should be supplied by the maker in such consistency that they can be worked in their full body. If inks are too stiff, they will pull the surface of the paper, and probably dry on the rollers. It is inadvisable for the printer to do much in the nature of reducing the inks. Should it be absolutely necessary, he should use a reducer supplied by the inkmaker, as reducing with oil and the like will take the body out of the ink, and the colour will dry very flat. The difficulty may often be overcome by placing an electric stove under the ductor; the heat somewhat softens the ink and make it work more freely.

Inks that are required for use on three-colour work must be specially made for the purpose, in order that the colours shall blend properly. If ordinary colours were used, one colour would not blend with another, as there is not sufficient transparency in them. Inks vary much in their nature of origin, some being mineral and others vegetable and chemical. [See INK, pages 4826 and 5075.]

Paper and its Treatment. The paper used for three-colour work in particular, and also for any colour register job, must be well seasoned, otherwise there will be contraction and stretching during the interval between the printings of the colours.

Coated art papers are chiefly used for colour printing because, having a highly polished surface, they show a good finished effect. Art papers vary very much in quality. Care must be taken in the handling and storing of art papers. They should be stored in a dry atmosphere, preferably at the same temperature as that of the press-room. Should paper be exposed to various atmospheric changes, it will undoubtedly give trouble in printing, both from register and the lifting of the surface. Care must be taken not to make breaks and creases in the paper when handling, both in the warehouse and between the printing of the colours, as this causes set-off and the depositing of the enamel on the forme, which, if not quickly removed, will spoil a number of sheets. It will be readily seen, therefore, that progress with the printing will be very slow if the paper is damp and peels badly, as the machine must frequently be stopped to clean the plates.

Some printers hang their paper for colour-work in half-quire lots; this is the best method to ensure paper being thoroughly seasoned, and consequently good register results. Of late years a dead-finished art paper has been on the market, but it is more used in the United States than in this country.

Bronze Printing. Gilding or bronzing is accounted one of the fine arts of printing. The process usually adopted for bronze or gold printing is as follows: the make-ready is as for ordinary letterpress work, but a special ink, called a *gold preparation*, is used, which is a kind of yellow-buff ink. The wet sheets are then dusted over with a pad dipped in bronze powder. In houses where much bronze-work is done, machines for depositing and for dusting off the bronze powder are used.

Of late years gold inks have been on the market, but, although simplifying the process, they do not give quite as bright a result as the ordinary method of bronzing explained above.

THE PUBLIC LIBRARIAN

Growth of Libraries. The municipal public library, in the English and American sense, is a speciality of Anglo-Saxon peoples. Only in recent years has anything of the sort existed on the Continent, and those which do exist are based more or less on English or American lines. These institutions are purely modern, even in England, dating no further back than the middle of the last century. It is true that there were free libraries in England in the early part of the seventeenth century, but they were due to private benefactions, were extremely limited in scope, and were not supported by a library rate. The rate-supported public library was created by an Act of Parliament passed in 1850. The man who introduced it was William Ewart, M.P. for the Dumfries Burghs. But the man who was mainly instrumental in creating an enlightened public opinion upon this subject was Edward Edwards, to whose memory a monument was recently erected over his grave at Niton, in the Isle of Wight, where he spent the last years of his life. Edwards became the first librarian of Manchester, the first library of importance instituted under Ewart's Act.

Libraries Supported by the Rates. The Act of 1850, like all the Library Acts which have been passed since, was an adoptive Act—that is, it gave a community power to adopt the Act by vote, and through its governing body to levy a rate of one halfpenny in the pound for the upkeep of the library. It was speedily seen that this rate was much too small for any effective purpose, and in 1855 an amending Act was passed permitting a rate of one penny in the pound to be levied. Despite the fact that this was sixty years ago, and that the work of public libraries has developed enormously in range and importance since, the limitation of the rate to one penny remains, and is the great stumbling-block to the further development and extension of these institutions. In the cases of about fifty-five of the large towns, powers of levying a rate up to twopence in the pound, or even more, have been obtained by the expensive process of special local Acts of Parliament.

About 708 towns and districts in the United Kingdom have adopted the Acts to date. Most towns of any size have had to supplement the service of the central library by means of branch libraries, and the number of library buildings in the great towns, such as Glasgow, Liverpool, and Manchester, is considerable. Altogether, it is likely that the number of public library buildings in the country approaches 1000. This includes rented premises as well as buildings specially built for the purpose. The latter have largely increased owing to the munificence of Mr. Andrew Carnegie. The total number of volumes in the public libraries of the United Kingdom in 1911 was 10,995,115, and the total number of volumes issued in the year ended March 31, 1911, 54,690,222. These figures, large as they are, give only a very partial measure of the work done. They leave out of consideration the enormous use made of the news and magazine rooms, and such "extension" activities as lectures. The total income of these libraries in the same year was £812,718, and the total expenditure was slightly over the income, amounting to £814,932.

Salaries. The conditions of service in municipal libraries are directly related to the size of the library or library system and the income. Libraries differ from most other departments of local government in that their income is a fixed quantity, and cannot be raised, however insufficient it may be to meet the needs. The number and remuneration of library staffs are governed by these factors. There are three public libraries with annual incomes of £10 or under, and there are more than one hundred libraries with incomes of £100 or under. In the best of these cases it is scarcely possible to employ more than one person, and he, or she, cannot be a trained librarian. At the other end of the scale we have huge library systems like those of Glasgow, with an annual income of about £37,726, and Manchester, with an annual income of about £35,078.

Leaving out of consideration the very small libraries, the staffs consist of a head librarian, a sub or deputy librarian, branch librarians, and senior and junior assistants. The salaries of head librarians, disregarding libraries of less than £500 a year income, range from £70 to £700. The latter figure is very rarely reached indeed, and there are very few municipal librarians receiving more than £500 a year. In some cases a house is provided in the library building. The salaries of sub-librarians vary from £40 to £300, and of branch librarians from £50 to £250. Senior assistants may receive anything from £35 to £170, and junior assistants from £13 to £60, or more. Women and girls are employed in many libraries, and their number is increasing. It was recently estimated that there were in all about 3500 library assistants in Great Britain, of whom 1500 were women. The figures of salaries given above apply to male assistants; in the case of female assistants they range lower. In a few libraries women are heads, at salaries ranging from £100 to £150, but these libraries are small, and it is not at all likely that the principal library positions will ever be open to women. This is the case in the United States, where women constitute the bulk of library staffs.

Hours. The number of hours worked by assistants depends to some extent on the size of the library and the number of the staff. The average is about 45 hours per week. Owing to the fact that most public libraries are open continuously from 8 or 9 o'clock in the morning till 10 at night, the staff must work in shifts, and evening duty is a necessary feature of library work. Most libraries close for one half-day, and it is usual for assistants to have an additional evening free. Vacations range from four or five weeks for heads, to two or three weeks for senior

assistants, and ten days or two weeks for juniors. In addition there are public holidays, when most libraries are closed, at any rate in the book departments.

Qualifications. The methods of appointment vary. The more important posts, if not filled by promotion, are advertised in the local or district papers, and generally also on the front page of the "Athenæum." Previous library experience and the possession of some certificates of the Library Association, or of the diploma issued by that body, are generally essential. Junior assistants are appointed from the locality, and in most cases are put through some sort of preliminary examination at the library. Any boy who wants such a position should write to the librarian in his town, or to some other librarian in the locality, and ask to be informed of any forthcoming vacancy, at the same time stating any special qualifications he may possess. Perhaps two of the best qualifications are the possession of some general information, such as may be obtained by any boy who reads the newspaper intelligently, and a knowledge of some of the great works of literature. The average boy of fourteen of today is so well supplied with books written specially for him that his knowledge of some of the great "grown-up" books is very small; the boys of an older generation, if they had the desire for reading at all, read far more widely, and gained much by so doing, even if, as happened many times, they did not altogether understand what they were reading.

It is, however, one of the commonest errors made in regard to library work to suppose that "bookishness" is the only qualification necessary. There is no department of the Local Government service which makes a greater demand upon the qualifications which make for success in business than does the public library. It is a fact not generally known that the outstanding characteristics of modern business organisation are due to the library. The card index, the loose-leaf ledger, various methods of filing, are all based on methods first worked out and applied by librarians; but, in addition to a love of books and a capacity for business, the true librarian must have an intelligence alert at every point, a large fund of miscellaneous information, and wide and catholic sympathies. As the public library is not only a recreative and educational institution, but is also an important form of social service, the librarian must also be imbued with the missionary instinct if he is to fulfil all the requirements of his office.

Training. The Library Association, which is the principal professional body, founded in 1877 and incorporated in 1898, organises or promotes lectures and classes in library economy, holds examinations, and issues certificates and a diploma. The examinations are limited strictly to librarianship in the technical sense, but a good general education is presupposed, and is essential for the efficient performance of the duties attached to any position in a public library above the grade of junior assistant. Examinations are held in the following six subjects:

1. Literary history.
2. Elements of practical bibliography.
3. Classification.
4. Cataloguing.
5. Library history, foundation, and equipment.
6. Library routine (practical library administration).

Certificates are issued for the examinations in each of these subjects, either for a simple pass, or a pass with merit, or with honours. Lectures are given every winter in London under the auspices of the Library Association, and are also held on various portions of the syllabus at Birmingham and Liverpool. For the benefit of students unable to attend lectures the Association organises correspondence classes. Lectures are open to anyone, and certificates granted, irrespective of work in a library. Students who possess the six certificates may enter for the diploma, but may be required in addition to undergo a further oral test. The student must also present a thesis showing original thought or research on some subject within the purview of the syllabus, previously approved by the Council of the Association. He must have worked for not less than twenty-four hours a week for at least three years as a member of the administrative staff of one or more libraries, and he must show that he possesses an elementary knowledge of Latin or Greek and one of the following languages—French, German, Italian, or Spanish. Further information with regard to the examinations, list of books recommended for study, and copies of the questions set may be seen in the "Library Association Year Book," published annually by the Association, price 1s. net.

The Work of a Junior Assistant. No description of the work carried on in a municipal library can apply to all libraries. In a very small library, where the staff is limited to a librarian and a single assistant, or even to a librarian only, it is clear that the division of work into junior and senior grades is inapplicable; the librarian himself must do everything. The larger the library, as a general rule, the more specialised the work. Moreover, the work of a progressive library, in touch with the most recent developments, will be much more varied and exacting than in the case of a library run on old-fashioned lines. One of the most striking differences of method, which may lead to variations of greater or lesser importance in the whole library organisation, is that between what is known as the "indicator" or closed-shelf system, and the "open-access" or free-shelf system. In the "indicator" system the shelves in the lending library are open only to the staff, and borrowers must apply for the books by number at a desk or counter; and in order to save the time of the staff it is usual to indicate whether books are "in" or "out" by means of columns of numbers in frames, the numbers being changed in colour, or underlined, or marked in some other way, according to the style of indicator in use. In the "open-access" system, borrowers have free entry to the books, which they choose themselves, and which are handed over to the staff counter either to be entered up against the borrower, or to be marked off if the book is being returned. For many years the "open-access" system was regarded by most librarians as a dangerous innovation, but extended experience has removed the prejudice against the system, and it is now being adopted in a great number of the recently opened libraries.

The principal duties of the junior assistant will be comprised in the work attached to the staff desk or counter, where the processes of entering the issue and return of books are carried on. In subscription libraries the most important record is kept under the name of the person borrowing, but in municipal libraries the principal, and generally the only, record is kept under the particular book borrowed. In the most common form of the indicator the particulars of the registered number of the borrower, and the date of issue, are written in a little book, attached

to a metal strip, containing the number corresponding with that of the book borrowed on the turned-up ends of the strip, which is inserted in a pigeon-hole in the frame. In open-access libraries, and in many indicator libraries where only a portion of the books (usually fiction) is represented by the indicator, cards are employed, and, by bringing the card representing the book and the borrower's ticket together in an envelope or pocket, the "charge," as it is technically termed, is made without any writing at all. These cards, thus temporarily "married," are inserted in trays behind the date of issue, and books which are overdue automatically show themselves.

The writing of notices to readers requesting the return of overdue books, and stating the amount of the fine to be paid, will be part of the work of the junior. In all these records great accuracy and care are required. The junior also in his contact with the public must learn to be helpful and polite, even under trying circumstances.

Another part of his work will be the replacing of returned books on the shelves. In an open access library it is usual for each junior to be responsible for a section of the shelves, and, as the books will be closely classified by subject, he will become acquainted at least with the titles of the works in his section, and so lay the foundation of a knowledge of bibliography. He will also have his part to play in the many processes through which books must pass between the time when they are received from the bookseller and the time when they are ready for the reader. This will include the examination of books for uncut pages, and the cutting of same—a simple process, but if carelessly performed a valuable book may be easily damaged.—the stamping of certain of the pages with the library mark of ownership, the pasting of the library labels inside the boards, and the tag or small label on the back of the book, which carries the marks by which the book is arranged on the shelves. Checking of newspapers and magazines is another branch of the junior's work. Other work is that common to all offices, such as stamping and posting letters, and similar office routine

The Work of a Senior Assistant. The term "senior assistant" may designate many different grades, but, as in a small library these may all be lumped into one, they are here described in bulk. A senior will usually have to put in a good deal of his time at the counter, and here he will supervise the work of the juniors. But in addition he will be engaged in most of the higher branches of librarianship. First, perhaps, in order of importance is *cataloguing*. As a junior he may have had some practice in copying the catalogue entries of books, and it may be said here that many persons never acquire the faculty of even copying anything accurately all their lives. Accuracy in small things as well as in great things is usually an acquired virtue, and it is the chief virtue of the library assistant. The senior, however, must be able not merely to copy what is given him, but also to learn to describe the book in proper bibliographical form.

Cataloguing. To write down the author of a book, the title, and certain other particulars seems a very easy task, but it is really an art in itself. It is not always easy to decide who is the author of a book, or under what part of the name, or under which name, an author should be entered, because authors very often write under pen-names, as well as under their own names; women writers who are married are another difficulty; noblemen may be entered under the titles they bear or under the family name, and there are dozens of problems of a similar kind which confront the cataloguer. Two of the fundamental principles of a properly compiled catalogue are that all books of an author shall be collected in one place, and that entries shall be made according to definite rules, and not in haphazard fashion. Otherwise the catalogue will be rendered largely useless as a key to the contents of the shelves. When the cataloguing is elaborate the number of such rules may be very great. There are many "codes," as they are termed, of rules, but the tendency now is towards uniformity, and particularly to the adoption of the "Cataloguing Rules: Author and Title Entries," compiled by committees of the American Library Association and of the Library Association, an English edition of which is published by the Library Association, price 2s. net. This code applies only to authors and titles; there are also rules published for subject catalogues. Rules for a printed catalogue must differ also to some extent from the rules for a manuscript catalogue. The latter are mainly to be found in the form of card catalogues, and a study of the card catalogue and the special problems connected with its compilation and guiding is in itself a large one. Nobody can learn to catalogue by reading a set of rules; one has to apply them to the actual books. In modern municipal library cataloguing, works are often annotated, and the subject of annotation has been specially treated. The ability to describe the idea and characteristics of a book tersely and truly calls not only for training but for a special quality of mind. This special quality of mind is perhaps still more necessary in the complementary art of *classifying*.

Decimal System of Classification. A quarter of a century ago hardly any libraries were closely classified; now close classification is common even in the smallest municipal libraries. Classification is a subject upon which a great deal of investigation and work has been done in recent years, especially in America, and one American system, known as the Decimal System, invented by Dr. Melvil Dewey, formerly librarian of the State Library of New York, is the most widely adopted. The principle of the system is that of indicating the subject of a book by a number, and it receives its name from the fact that just as the position of a figure in relation to other figures determines its order, whether in the units, in the tens, hundreds, and so on, so the position of the figure in the Dewey class-mark indicates its position in the order of the headings of the tables of subjects, whether class, division, or section; and the decimal analogy is followed by using the point to indicate the minute sub-sections of the scheme. Thus books of Self-Education and Culture are 374, and this number analysed breaks up into class 300, Sociology; division 70, Education; section 4, Self-education; and while 374 would mark all general books on the subject, books on special aspects of it would be indicated by a number beyond the decimal point. Thus 374·4 would be 374 as above, and ·4 would mark Correspondence Teaching. It will be seen that new headings may be inserted at any point by simply adding another figure on the right of any existing mark. The classification can also be carried just as far as convenient, and the number of books on a subject and the circumstances of the library will determine the degree of minuteness of the classification. Even small libraries will employ from 1000 to 1500 headings, but large libraries will use many more. The library assistant cannot know all these headings without reference to the

tables, but he must understand the proper use of the tables, and must be able from inspection of the book to give it its correct class-mark. It is impossible in the space allotted, nor would it be of much practical service, to enter further into this subject, or to notice other rival schemes which have been prepared. The same general principles govern all modern schemes.

Binding. It is impossible to leave even this cursory sketch of the work of the senior assistant without a reference to the department of binding. The binding and rebinding of books is naturally a large item in the municipal library, and the senior must know the best leathers and cloths to use in relation to the particular book to be rebound, and must also understand the various binding records, be able to draw up the necessary instructions, detail the lettering to go on the back, and finally check the binding on return.

The Work of a Chief Librarian. Little can be said in the space available of the work of a librarian. He is the link between the staff and the governing authority, and it is the business of the librarian to be responsible for the carrying out of the committee's instructions. As a general rule, committees confine themselves in the main to questions of policy and finance, and leave to the librarian the practical details of administration. Apart from the supervision of the staff and building or buildings, one of his most important duties is concerned with the selection of the books which shall be bought. The librarian usually submits a list of suggested purchases to a Books Sub-committee, and books are only ordered when their approval is obtained. The money available for new books in the majority of cases is inadequate, and the task of selection is naturally rendered more difficult because of this. The basis of the librarian's selection will be reviews in the various literary and scientific papers, suggestions from readers and experts, personal examination, a knowledge of the books already in the library, and of the special circumstances of his locality. Experience, judgment, and broad-mindedness are necessary if the funds of the library are to be expended to the very best advantage.

In the early days of the public library the emphasis, both in buying and in home circulation, was on fiction, but in recent years the percentage of fiction read has been gradually dropping, and in some towns is now surprisingly low. This is partly due to the extending use of libraries for educational purposes, and partly to the greater proportion of money spent on non-fictional literature. The average proportion of the book fund—excluding the reference department—spent on fiction may be taken as about one-third. Only the best novels are bought, the circulation of fiction of third and fourth rate value being rightly left to the commercial circulating libraries.

The general aim of committees is to form as representative a selection of books as is possible within the means at their disposal.

In regard to subjects which divide themselves sharply into *pro* and *con* divisions, and relate to the hotly debated political and social topics of the day, it is the duty of the public library to provide the best and most authoritative expositions on every side of the question. In certain directions, depending chiefly on local circumstances, every library but the very smallest specialises, generally on the principal trade or industry of the district, and on the town or county history.

There are always collections of books for children, and in many places these are shelved in children's reading-rooms. The number and variety of books written for children is one of the distinguishing features of modern publishing; and owing to their scanty and unsatisfactory treatment in the literary papers, this is one of the most difficult departments of selection, and at the same time one of the most important. A grown-up reader is either immune from rubbish or his taste for it is beyond cure; but the taste of the young reader is as yet unformed, and he can only be taught to like what is good by having only what is good put before him.

The selection of books for a reference library raises problems somewhat different from that of books intended to be taken and read at home. The amount of money available will still more rigorously dictate the lines of selection. If this is small, a representative reference library is impossible, and the attempt at it should not be made. The books bought should be those which give the most varied information in the most compact and convenient form—namely, encyclopædias, dictionaries, and the like.

There are many departments of library management not even mentioned in the foregoing paragraphs, but enough has been said to give the reader a general idea of the kind of work done in libraries. As the details of salaries given earlier on in this article will have clearly shown, the profession of librarianship is a poorly paid one; it is, however, gradually improving, and for one who is drawn to the work it has many compensations.

Organisation of the Profession. The Library Association, whose offices are at Caxton Hall, Westminster, S.W., is, as already stated, the principal professional body. Membership is of three kinds or orders. Under the regulations which now apply, Fellows are persons who possess the diploma of the Association; and Members are persons who possess any four certificates of the Association, and who have had three years' approved library experience. Associate Members are either librarians who are not qualified as Fellows or Members, or persons who are not librarians but are members of library committees or boards, or interested in libraries or in bibliography. The Association is in no sense confined to municipal librarians, but is representative of every class of library. Fellows and Members pay an entrance fee of one guinea, and an annual subscription of one guinea; Associate Members pay an annual subscription of one guinea and no entrance fee. All members receive free "The Library Association Record, a Monthly Magazine of Librarianship and Bibliography," published by the Library Association, price 2s. net per number.

Library assistants have their own association, the Library Assistants' Association, whose membership is confined entirely to assistants in libraries, or chief librarians who have been hitherto members or associates of the Association. Membership is of three grades: Fellows are chief librarians, as aforesaid. Members are persons engaged in library administration other than chief librarians. Associates are persons engaged in library administration other than librarians, whose salary does not exceed £55 per annum. The annual subscriptions are 7s. 6d., 5s., and 2s. 6d. respectively. "The Library Assistant," published monthly (annual subscription 4s.), is the official journal of the Association. The secretary is Mr. W. Benson Thorne, Public Library, Brunswick Road, Bromley, Poplar, E.

L. STANLEY JAST

Taxidermists and Naturalists. Tobacconists. Toy Merchants. Undertakers.

ENCYCLOPAEDIA OF SHOPS—10

TAXIDERMISTS AND NATURALISTS

A LARGE town, preferably a port, is the best place for the business of a naturalist and taxidermist; and for the sale of smaller specimens, such as mounted butterflies, moths, and beetles, proximity to a large college is an advantage. The business is usually started in quite a small way, often in a private house, and, except in specially favourable centres, there is very little room for a business of any pretentious size. This being so, nothing can be said as to the capital necessary to begin as a taxidermist. Everything in this business depends upon personal skill and effort. The prices, too, at which specimens are sold vary tremendously, and no standard can be followed. The cost—time of taxidermist, materials used, and proportion of overhead charges—must be worked out, and a reasonable margin of profit added. The all-important qualification for success is skill in preparing specimens.

In attempting the practice of taxidermy, the best subject for a beginner to experiment on is a bird—not too small or delicate—such as the common starling, the feathers of which are not difficult to handle, and the skin fairly tough.

The tools [1] necessary are a sharp-pointed knife—a penknife will do; a pair of strong, pointed scissors; a sharp-pointed awl or pricker; a pair of side-cutting pliers for cutting wire; a pair of tweezers for arranging the feathers; a file and a needle. We shall also require some cotton-wool and wire; some pins and glass eyes; tow, wood-wool shavings, similar to those used for packing; some strong thread and soft cotton; powdered alum, arsenical soap, fine sawdust, and a little plaster of Paris.

Preparing the Bird. The first operation is to put a thread through the nostrils of the bird, making a knot, and leaving a loop as long as the neck and body of the bird. The loop will be of great assistance in returning the head when the body is skinned. Plug the nostrils, throat, and any shot-holes with wool. If the body is very moist, use a little sawdust and plaster of Paris to absorb the blood. Break the wing-bones (the humerus) close to the body. Make an incision in the middle of the breast [2], first blowing the feathers apart, and continue the cut to the vent. Care must be taken not to cut too deeply in the abdomen, or the intestines will protrude, and give great trouble by making the feathers dirty; sawdust and plaster should be applied to prevent this. The skin should be pressed back with the side of the knife. No further cutting will be necessary until the tail and the legs are undertaken, when the scissors should be used to snip the tail-bone. The legs should be pushed up, and the first joint exposed must be cut with the knife.

Remove the flesh from the leg down to where the feathers end, return the leg-bones to the skin, and proceed to press the skin away from the back. Cut through the wings where broken, and turn the skin inside out down to the head, holding the body between finger and thumb. Great care must be taken not to split the skin in getting it over the head. The ears will first be met and cut through; then the eyes, which require still more care. Skin down to the bill [3]. Cut through the base of skull, and remove the neck. The brain, tongue, and eyes should now be removed, and the sawdust and plaster brushed off. Apply alum to the skin if very moist or not quite fresh; anoint all bones and the inside of the skin carefully with the arsenical soap, and place a ball of wool in the orbit of each eye.

Variations of Method. Certain birds, such as ducks and divers, have very large heads and long, narrow necks. It will be found quite impossible, in skinning them, to get the skin of the neck over the large head.

In this case, skin as much of the neck as possible; then cut it off, return the skin to its natural state, and smooth the feathers.

Now proceed to skin the head by making an incision starting at the ear, and continuing the cut down the neck just far enough to have the opening large enough to press the skull through. After removing all the flesh, the eyes, and the contents of the brain-box, anoint all parts with arsenical soap, then place the pads of wool in each eye, and return the skull to the skin, and carefully sew up the opening made. If care be taken, no sign of the seam will be noticed when the bird is finished.

In all birds above the size of finches the wings will require skinning. In the smaller birds the amount of flesh is so small that it dries in a very short time.

The opening is made on the under side. Place the wing flat on the table, fix it down by placing a weight on the quill feathers, then extend the wing to its fullest. With a sharp-pointed knife make an incision, beginning at the last joint of the wing; make the cut between the rows of feathers, cutting towards the body, taking care not to cut any of the feathers. The flesh can be removed in strips if the sinew is cut at the end of the joint; care must be taken not to cut the skin on the outside of the wing, or some feathers will fall out. After anointing the bone and skin with arsenical soap, a little chopped tow should be used to replace the flesh, and then the skin neatly stitched together, being careful not to sew any of the feathers down with the thread.

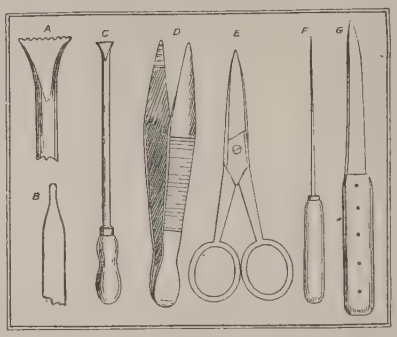
In skinning birds with white breasts, such as gulls, divers, and some kinds of ducks, it is better to make the opening on one side, as the purity of the breast will then be preserved. Make an incision under the wing, and continue down to the vent, then proceed as previously described. The skins of most water-birds are always very greasy, the fat clings to the inside of the skin, and the quills of the feathers projecting into it render it a troublesome task to get it off. A knife must not be used on account of the quills, which if cut will cause the feathers to drop out. Use an old rasp, rub the skin gently; the motion should be from the neck of the bird to its tail. After a time the fat will begin to collect on the rasp. Now sprinkle some sawdust on the skin, and continue the rubbing; the sawdust

will gradually absorb the grease. Throw away the greasy sawdust, and add clean until the skin is free from fat.

It is necessary to remove all fat from the skins, as, if left on, it will not allow the preservatives to act, and the skins will become rotten and brittle. Benzoline will clean the edges where the feathers may have become soiled.

Stuffing. Now lay the skin on the table, and return the skull to its proper position; the loop of thread in the nostrils will assist this operation. Coax the skin with finger and thumb over the skull, and the whole skin will, with a little shaking, return to its natural position. Smooth the feathers of the head the right way, and work the body-feathers downwards into position. Now make an egg-shaped body the size of the one taken out, using the wood-wool for this, pressing it together tightly, as the leg wires must depend on it for fixing firmly. Cut a wire twice the length of the neck and body, and point it at both ends. Drive the wire through the body, make a loop, return it, and then clinch it.

Wind a little tow round the wire to form the neck, being careful not to make it longer than the one taken out; and drive the wire through the centre of the skull and work the skin down over the body. Cut two wires three times as long as the legs, point at one end, and insert one underneath each foot, working it up the back of the leg; a little tow must be wound round the wire and bone to make up the flesh removed from the thigh-bone. The wire is now driven through the body, out under the opposite wing, turned, and pulled back into the body. A slit must be cut in the skin to allow the loop to pass and so leave the skin free. Insert a little pad of tow in the base of the tail, and sew up the skin, taking care not to sew down any feathers. The legs should be bent into their natural positions.



1. TAXIDERMIST'S TOOLS

a. End of stuffing iron *b*. Section of stuffing iron *c*. Complete stuffing iron *d*. Tweezers *e*. Scissors *f*. Pricker *g*. Skinning knife

When the operator has reached this stage, he will be able to judge if he has made the body the right size. The skin should have met easily over the hard, oval body, and usually a little additional stuffing is required, which can be easily inserted through the small slits which have been made under the wings to allow the wire loops fixing the legs to be pulled into the body. Always use chopped tow for the additional stuffing, using a small stuffing-iron to work it in through the slit into position. On no account should cotton-wool be used, as this material felts into a hard lump, and is not easily moved about under the skin; its worst feature is that it is difficult to penetrate when in subsequent operations the wires and pins for fixing the wings are inserted.

Mounting. The bird has now to be fixed on a twig or a perch. Two holes are bored through the perch to take the leg wires, and the wires are twisted firmly to the perch. The tail must now be adjusted, one—and sometimes two—pointed wires being used to fix it in position. The wings require two wires each, one through the shoulders, the other near the roots of the primaries or quill feathers. Fix both wings the same height, or the bird will appear lopsided when completed.

The throat may be filled out from the mouth with tow, finely chopped with scissors, and the cheeks filled from the eye. The eyes are then inserted, and the tail expanded to the required width between two slips of cardboard.

The final binding with cotton is next, a long pin being inserted in the back, and one or two in the breast, keeping to the centre line of the body. The pins, with the four long wires, and the wire protruding from the bird, are utilised in winding the cotton round the bird to compress the feathers gently into place while the bird is drying [4]. The novice must not expect his first bird to be a great success, or perhaps his sixth or twelfth, for, simple as the operation may seem, it requires practice to get the natural shape and pose.

Foreign Birds. For brilliance of plumage the palm must be awarded to the foreign birds. They are usually brought to this country as dried skins, and before they can be mounted require to be relaxed by moisture. This may be accomplished with ease. Wrap each bird in paper; prepare a box containing damp sawdust, or, as an alternative, damp sand; cover each bird with the damp material, and after forty-eight hours examine to find if the skins have absorbed sufficient moisture to make them pliable. A good test is to try if the toes will move easily; if this is so, then the seam in the abdomen may be opened, and the material with which the skin has been filled may be carefully removed; a pair of tweezers are very useful for this.

In removing the stuffing great care is required in order to prevent the skin tearing; in foreign birds this is very brittle until fully relaxed. A short piece of stick, and sometimes a wire, will be found inserted in the neck; in removing this, great care is required, as it may come away with a jerk, which might easily tear off the head. When empty, the skin should be filled with damp sand or sawdust, and replaced in the relaxing box, in order to allow the skin to absorb enough moisture to enable it to be handled with safety; twenty-four hours should be sufficient for this. The skin should then be turned inside out and scraped, especially the roots of the feathers, adding a little moisture in order to make the skin quite pliable. This is a most important point, and one which must not be omitted; the fact must be realised that the skin has become shrunken in drying, and before one can help to make it a lifelike specimen it must be well stretched and softened. Arsenical soap may also be worked into the skin; this will be of great assistance in softening it.

To stuff and mount foreign birds, proceed as described for fresh skins, but the difficulties to be encountered are a more stubborn skin, and one which has been dried in an unnatural shape, requiring more than ordinary patience to overcome.

Animal Stuffing. Small animals up to the size of a rabbit will require the same tools and materials as those required for mounting small birds. Before skinning, an outline of the animal should be made by laying it on a sheet of brown-paper as nearly as possible in the position in which

it is intended to mount it, and its shape marked with a long pencil or crayon, the size of the body being marked on this sketched outline.

Always skin an animal down to the toes. The tails in small animals can be drawn without cutting them open. The lips must be split, and moist clay inserted to give them fulness. The ears must be skinned, and clay used to replace any flesh taken away; sheet zinc, cut to the proper shape, is used to stiffen and keep them in position. Always keep the leg bones on the skin, as they are invaluable in shaping and posing the animal.

The hard, egg-shaped body used in bird-stuffing is not used for stuffing animals. The head and body wire is twisted in tightly with the fore legs first, then the hind legs. The length of wire used must allow for fixing the animal upon the stand.

The neck and body are gradually filled with chopped tow, wood-wool, and sometimes with hay, keeping the shape and ultimate position in view. Never use tow without chopping it up small, or it will form an immovable ball inside the skin, and show an ugly lump; cotton-wool, too, should be avoided for the same reason. Soft pipeclay is very valuable in the head, feet, and those parts where such details as muscle must be shown. Always use annealed iron wire, thick enough to give stability, and bear in mind that it is easier to add a little stuffing than it is to get it out.

2. BIRD-STUFFING: THE FIRST INCISION
a. Thread loop tying up beak

3. BIRD-STUFFING: SKIN TURNED INSIDE OUT
a. Point to cut head from neck
b. Thread loop to assist in returning the skin

The hair must be cleaned and brushed and combed in its natural direction while the specimen is wet; blood and grease must be washed out before stuffing. Fat left on the inside of the skin prevents any preservative acting properly, and will cause the skin to rot. It is better to allow the skin to remain a few hours for the alum to act on it before applying the arsenical soap. The action of alum is astringent, shrinking the skin and so fixing the hair firmly by the roots; it will also extract the surplus moisture from the skin, but any crystals remaining undissolved are better brushed off before applying the arsenical soap. The eyes, ears, lips, and toes require special attention, to see that the alum is worked in well. If the skin cannot be stuffed immediately, do not let it remain folded on itself; place a little hay or tow inside it to prevent the inner surfaces touching. If this is not done, the skin will sweat, decompose, and the hair will fall off at the slightest touch. The leg bones must also be wound round with tow.

Larger Animals. The larger animals require a different treatment; the legs in animals the size of deer and larger must be opened right down the inner side, so that the seam is least noticed when mounted. The irons for the legs will require to be tapped, and two nuts fitted to each leg, to give the support to carry the weight when fixed up. The irons must be bent to the proper curves and angles, which the paper outline will give. A board, about 2 in. thick, must be cut to the shape and size of the body. The leg irons are very firmly fixed to the board by iron staples, as also is the iron for the head and tail. The head iron is brought through the skull by passing it through the nostrils, and is cut to its proper length when the head is finished [5].

The bulk of the body is made up by fixing dry straw to the body-board. It must be tied securely round the board with string, shaped as nearly as possible to the pattern and measurements, and made a little under the proper size [6]. The skin may now be tried on, and if the edges meet comfortably, and the legs are the right length, the skin may be sewn up. Begin sewing at the neck and work downwards.

The dried skins of the larger animals are very stubborn, and require to be pared down with a spokeshave, the skin being laid on a short length of a scaffold pole. A knife must be used for the more important parts, such as the ears, the eyes, and the nose; and the lips, if they cannot be split, must have linen sewn round the edges to form the pocket for filling with clay.

Fish Stuffing. The stuffing of fishes is one of the most difficult branches of taxidermy, and it will try the patience and skill of the novice to the utmost.

The fresh-water perch is a good species to experiment with. Choose the best side for the show side, and mark its outline on a sheet of paper as a guide. Make a cut on the other side with a strong pair of scissors, down the middle of the body from the centre of the gill-cover to the root of the tail. Use a knife to free the skin from the flesh, and cut from tail to head. The skin of a scaly fish must not be turned, as in birds and animals, or the scales will be disturbed. The root of the tail and fins must be cut with the scissors inside the skin. See that the points of the scissors do not cut the skin, or a few scales will drop out. The gills and all the bones of the head must be cut away with the scissors. When the skin is ready, it must be soaked in water to remove any blood and slime that may adhere to it. All loose scales should be saved, as they will perhaps be wanted for repairing the skin. There are several methods of stuffing fish, and one of the simplest of them can be used for fish up to the weight of 5 lb.

Damp Sand Method. Take fine yellow sea-sand, damp it so that it is just tenacious enough to retain a shape when grasped by the handful. After using arsenical soap on the skin (alum should not be used for fish), sew up the skin a few inches at the head, and also at the tail. Place a loose ball of tow in the mouth to keep the sand from coming out, and fill the skin with the wet sand, pressing it tight and modelling the shape as the filling proceeds. Finish the filling in the middle of the body and sew it up. The fish must now be turned over on a board, a little longer and wider than itself, on which it is to lie and dry. Pat the head into shape, and work the body downwards to its proper curve. Fish skins always tend to become longer, and this must be prevented, or the result will be a failure. The fins and tail must be extended and fixed between two pieces of cardboard, pins being used for fixing them. The fins and tail must not be allowed to dry during stuffing, as in this state they are very brittle, and cannot be extended properly.

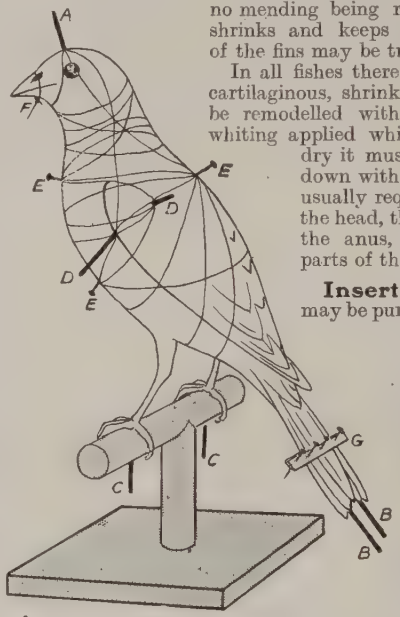
When the fish is properly fixed, a thin coat of gelatine, melted in warm water, will keep the scales in position. The fish must now be placed on a warm shelf to dry slowly, and examined occasionally to see that it is drying smoothly.

When the fish is dry, remove the sand by opening the seam and gently tapping the body. It is then

filled with tow, wood-wool, etc., and the seam glued together and covered by a strip of linen. A small wooden block to which are fixed two wires is also glued on the seam for fixing up the fish in a case.

The finishing and colouring of fish require much practice, and it is easy to overdo the colour. Use, whenever possible, transparent oil colours and a clear "crystal" varnish. The belly colour is the most important point to get right. It is usually white, and is shaded gradually to the colour of the sides. The eyes must be of the same size as in nature; the orbit of the dried fish is always larger than in nature, through shrinkage, so it must be filled up to its proper size with a composition described later.

Use of Plaster of Paris Mould. Fishes, especially those with a smooth skin, may be stuffed with the aid of a plaster of Paris mould, and this is undoubtedly the method by which the correct shape can be obtained. Place the fish on its side on a board slightly larger than the specimen, choosing the side least damaged for the show side. Arrange the tail and fins in a natural way on pieces of cardboard supported by wet clay. Bank clay around the fish so that it presents the appearance of a half relief; then fit strips of wood round, forming a rough box to keep the liquid plaster within bounds, making it water-tight with wet clay. When mixing the plaster of Paris do not add the water to the dry plaster; this is likely to cause hard lumps to form. Have just sufficient water in a bowl, and sift the plaster gradually into it; when sufficient plaster has been dropped in an island will be formed; this is the signal to begin stirring. When thoroughly mixed, pour it slowly on to the prepared fish, covering it with a layer about one inch thick for small fish, but thicker for a large mould. Give the bare board a few sharp taps; this will remove any air bubbles in the liquid plaster. In about one hour the plaster will be set and the fish may be removed. The result should be a perfect mould of the specimen.



4. STUFFED BIRD READY FOR DRYING
a. Head, neck and body wire *b.* Tail wires *c.* Leg wires *d.* Wing wires *e.* Pins to keep cotton in position *f.* Thread to fasten beak. *g.* Cardboard slips to hold tail feathers

When the fish has been skinned and cleaned ready for stuffing, the skin should be laid in the mould, which has been previously oiled. Fix the fins and tail in position with pins; now prepare a piece of wood for the body, shaping it to reach the root of the tail. Wood-wool may be tied on to the body-wood to make up the shape to within half an inch of the original. Mix a small quantity of plaster, and pour it on the skin in the mould, then place the wooden body in and press it down; the plaster will then fill out the skin to take the shape of the mould. A suitable weight may be used to keep the body-wood down while the plaster is setting. The skin can be drawn together in the next operation, and the filling may be pressed in to make the reverse side correspond in thickness and shape with the front or show side.

Treatment of Fins and Tail. The fish should now be fixed on a board with two screws driven through from the back of the board into the wood inside the fish.

The fins and tail can now be expanded. Cut the cardboard slightly larger than the fin, then paste the under side; now fix tissue paper on by turning it over the edges of the cardboard. Be careful to keep the upper side free from paste. The fins and tail may now be expanded and fixed with paste on the tissue paper; a few pins will help to keep the more obstinate rays in position.

The advantages of this method is that the operator can see all the fins after fixing, and can therefore judge the effect better than if they are covered in by cardboard. Also, when the fins are dry, a knife can be passed between the tissue paper and the cardboard leaving the fins free and perfect, no mending being required. In drying, the paper shrinks and keeps the fin quite flat. The edges of the fins may be trimmed with a pair of scissors.

In all fishes there are certain parts which, being cartilaginous, shrink very much; these parts must be remodelled with a composition of glue and whiting applied while warm; after this is quite dry it must be made smooth by rubbing down with glass-paper. The parts which usually require making up are the top of the head, the mouth, the fleshy under jaw, the anus, and, in some fishes, certain parts of the gill-covers.

Insertion of Eyes. The eyes may be purchased from the manufacturers, but require to be coloured for each individual. The pupil is always round in these ready-made eyes, but in very few fishes is this so in nature; therefore the pupil must be shaped with a very fine brush, using blue-black for the purpose. Some fishes have pupils slightly pear-shaped, others quite oval. When the paint is quite dry, proceed to tint the glass with the required colour, using a fine brush, with a stippling motion, and again place aside to dry.

Before the eye is placed in the fish, fill the orbit with cotton-wool, on the top of which is laid a small piece of silver leaf; place the eye on this, and press it into position, then fix all with the best composition of glue and whiting. The backing of silver leaf will give a more transparent effect than silver paint.

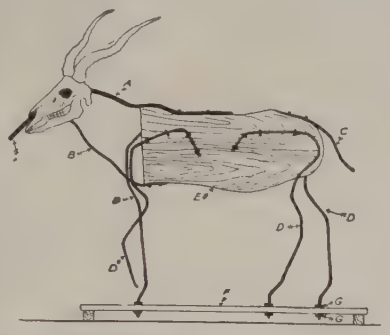
Some very natural fishes' eyes may be made by using the convex glasses sold by jewellers for fitting into lockets; these may be coloured on the concave side as described, and usually result in a more natural appearance than the thicker glass eyes.

Colouring the Fish. Undoubtedly the most difficult task is the colouring of a stuffed fish. If this is not done properly, all the previous good work is nullified. The knowledge of the blending of the various colours is essential. In most fishes the skin and scales, when dry, lose all the brilliant colouring and the silvery sheen. To replace this, the fish must be coated with aluminium leaf (sold in books similar to gold leaf). Do not use silver paint, as even the best kinds only give a dull, leaden effect, and will not keep bright. Give the

fish an even coat of gold size, omitting the fins; allow the size fifteen minutes to dry partially—when it is ready it will feel tacky to the finger.

Open the book of aluminium leaf and apply the lower portion of a leaf, bending the book quickly and firmly over the surface to be covered. The aluminium will readily cling to the tacky surface. In applying the next leaf, cause it to overlap the first at its edge, and so on, until all the fish is covered, including the abdomen; then with a pad of cotton-wool gently dab all the coated surface to ensure a perfect contact, and so induce the leaf to reach various hollows.

The work must now be put aside for a few hours until the gold size is quite dry, when the surplus leaf should be gently brushed away with a camel-hair brush. If any portion should show patches which are not covered with leaf, these must be coated with fresh gold size, and a portion of leaf applied. The joints of the leaves should not show if proper contact has been made and the leaf has been applied without crumpling it.



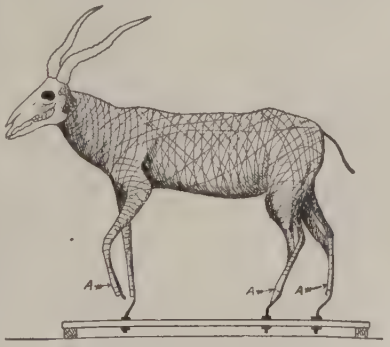
5. ERECTION FRAME FOR AN ANTELOPE
a. Head iron *b*. Neck iron *c*. Tail iron *d*. Leg irons *e*. Body-wood *f*. Temporary stand *g*. Leg iron nuts

Application of the Colours. Whenever it is possible, a live fish should be used to copy, as in all fishes the colours fade immediately after death. If the fish is one which is difficult to obtain, a water-colour sketch should be made of it before skinning; this would be a little guide to colour from, especially for the distinctive marking, such as spots and bars on fins.

Begin by colouring the belly with flake white, blending upwards; all the fins should be whitened. The fine-pointed sable-hair brush should be used to outline the scales. If the fish is a silvery one, use Payne's-grey, but in fishes whose prevailing colour is pink or brown, rose-madder or Vandyke-brown should be used respectively. When the scales are all marked, allow the paint to dry. Some oil colours are very slow in drying. Gamboge, black, Vandyke-brown, Prussian blue, crimson lake, and rose-madder all require a little terebene added to hasten the drying.

In applying the colours, begin with the lighter shades; for instance, if the fish is to be brown, apply first thin gamboge, then blend in Vandyke-brown, starting near the dorsal fin. Then, if a tinge of green is required, use Prussian-blue. The secret of success is to apply the colours very thin, bearing in mind that it is easy to darken them if necessary. Use a large brush, and apply the paint with a stippling motion to prevent streaky brush-marks showing.

When the paint is quite dry, give the whole a coat of crystal varnish; this will bring up the colours and give a transparent effect. When mounting fish in cases, etc., the best colour for the background is pale green, streaked horizontally with light blue to represent water. An artistic effect can be produced if rushes and weeds are painted on, and a few light strokes of the brush containing green passed over them horizontally to give a watery effect.



6. MANNIKIN READY FOR SKIN
a. Artificial leg-bones of wood

Preserving Fishes and Reptiles Entire. The use of formalin (formaldehyde) is now very popular for preserving fishes and reptiles. It has its disadvantages, however. If the solution is too strong, it shrinks the tissues very suddenly and distorts the specimen, which cannot afterwards be relaxed. A 10 per cent. solution is quite strong enough for general purposes. This proportion is not poisonous (a great advantage); and if the skins of fishes are soaked in it for a few hours before stuffing them, the scales will be firmer, and flies and other insects will be repelled. It is largely used to preserve small fishes for use as spinning baits for anglers. The specimens should be laid flat on a dish and covered with the solution. When it has acted enough to stiffen them, they may be placed in large jars with fresh solution, and sealed.

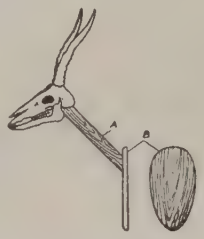
Plaster Casts of Fishes. A cast of a fish is always a more faithful reproduction than a stuffed specimen, as there is no shrinkage to spoil the effect, and consequently very little making up is required. Follow the previous instructions given for making the mould, but special attention will be required to ensure that the cast, when made, will be easily removed from the mould without breaking. Cut away and make smooth projecting parts of the mould which are not included in the shape of the fish, and fill in with clay any holes which are dangerous and likely to cause the cast to cling to the mould. Then give the inside of the mould several coats of French polish—this will create a hard working surface, and prevent the oil soaking into the mould. Linseed oil is very good to use on the mould.

Prepare a wooden body as described for stuffed fishes, but in addition cut strips of coarse canvas to place in the tail and fins to strengthen the plaster. When everything is ready, mix the plaster, and pour in sufficient to give a coat of about half an inch to every part of the mould. Then press down the wooden body; now place the strips of canvas in the fins and tail, being careful that a good thickness of plaster is available.

The canvas and the body should be quite covered in with the plaster, and the whole left to set. Then the mould may be removed by gently tapping it. While the plaster is still wet, the cast may be trimmed with a sharp knife. The fins should be bevelled to give an appearance of thinness from the front view, but the finer details had better be left until the plaster is quite dry and firm. Give the cast a coating of thin soap, then a coat of French polish, before proceeding to colour it; this is necessary, as

plaster is so absorbent. Silver and colour it as described for stuffed fishes.

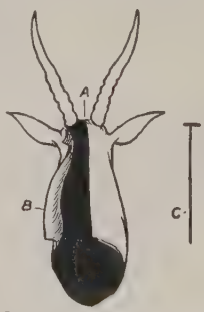
Mounting Animal Heads. If the animal has horns, it must be skinned by having a cut made up the back of the neck until it is level with the base of the horns, when a T-shaped cut must be made up to each horn, and continued round the bases to free the skin, so that the skull comes away entirely from the skin [8]. Remove the flesh from the skull, which must be boiled until thoroughly clean, and when it is dried it will be ready to mount inside the skin. The skin is rubbed, first with alum and then with arsenical soap, and the ears fitted with zinc and clay.



7. WOODWORK FOR GAZELLE HEAD
a. Quartering fixed in skull *b*. Back-board

Heads are fitted up differently from those of animals stuffed entire. Thick wood takes the place of iron for the support, and a piece of quartering, longer than the neck, is fixed in the skull, and several long screws driven at right angles through the bone into the wood. Cut a board not less than 1 in. thick, nearly the shape of an elongated egg, and trim off all sharp edges smoothly. This is called the back-board, and must correspond with the size of a cross-section of the neck at its extremity [7]. The quartering, having been fixed in the skull, must be cut to the length of the neck. The neck should be as long as the skin will permit; short necks look very bad, and an animal stuffed with a long neck can be made to look much more lifelike.

The skull, as at present fixed, should be hung on a wall, to find if the quartering is cut to the proper angle, so that the neck may be given a graceful curve. If there are horns in the specimen, the points can be brought to within 2 in. of the wall with safety. Horns do not always grow evenly, but it is possible to rectify this slightly while fixing up the skull. When everything is satisfactory, wood-wool is bound round the quartering to the shape of the neck [9], the skin is fitted on, and sewn up. Begin the sewing at the horns, and work down to the back-board; any stuffing which the neck requires must be inserted before the skin is fixed to the back-board. Three-quarter-inch French nails are the best to use for fixing the skin, as in drying the skin strains very much, and would pull shorter nails out. The cheeks are stuffed from the mouth and eyes, and the head finished as in entire specimens, plenty of clay being used in modelling the eyes, nose, and mouth. The glass eyes should be put in after the skin has dried, on account of the shrinkage during drying.



8. SKINNING A HEAD
a. Cross cut *b*. Skin partly removed *c*. Shape of cut

The shrinking of the skin is the bane of the taxidermist. The chief causes of shrinking are insufficient paring down of the skin, using clay too wet, stuffing the specimens too loosely, and not fixing and sewing up the skin tightly.

Before colouring the eyes, nose, and mouth, the specimen must be cleaned and beaten thoroughly. White French polish and methylated spirit in equal parts, and dry powder colours, are the best materials for colouring. Use stiff hog-hair brushes to work the colour in, and do not forget that the colour will, when dry, be half as light again when the spirit evaporates, which it does quickly. A little varnish will be required on portions which in nature are wet, such as eyelids, nostrils, open mouths, and lips. The horns are cleaned with soda-water, and rubbed with linseed oil and turpentine, to darken them.

Finishing and Casing. Cases should not be cramped, plenty of room being allowed for rock-work, glasses, and fittings, in order that they may be displayed in a natural way.

The case had best be made by a cabinetmaker; the wood used mostly is deal. Insist on having the best material and workmanship, as a faulty case will spoil everything. Panel backs to all cases are best, as splits in the wood are thus avoided. The back is lined with calico, carefully stretched and fixed with glue and tacks. When this is dry, paste white lining paper evenly over the calico. All the wood-work which is inside, except the bottom, must be coated with size mixed with powdered red lead; if this is not used the resinous matter and knots of the wood will show through the paper and make ugly spots. The inside of the case should be coloured with water colours, and a landscape may be represented.

Rockwork. Rockwork is made with brown-paper supported with wood, and in large work the basis is canvas, covered with paper wetted with warm water, and laid on evenly with glue. Considerable taste and practice are required to get the appropriate angles and curves to imitate different forms of rock.

When the glue is dry, the basis is quite stiff enough. Melt some size by adding one-fourth its bulk of water; add slowly to it crushed whiting until it has the consistency of gruel; apply this *hot* to the prepared basis. Have some dry sand, yellow or silver, according to the rock you wish to represent, heated to a temperature comfortable to handle, and throw it forcibly on the hot composition. When cold, gently knock the rock-work, and all sand which has not adhered will fall off. Colours ground in oil will do for colouring the rock-work. Do not overdo the colours—follow Nature in every way.

9. GAZELLE HEAD
Ready for skin to be fitted on

Grasses, ferns, rushes, and boughs must be thoroughly dry before using, and may be coloured with oil colours to which a very little varnish is added. Avoid stiffness; everything should look as if it were growing. This portion of the work is one which requires and deserves as much time as possible to be devoted to it.

The glass should be cut to fit the case exactly, and fixed by strips of wet paper of the same colour as the case. Black is by far the best colour to show up most subjects. The paper is applied with very smooth paste made from ordinary flour. As the paper shrinks in drying, it gives a stronger fixing.

Cleaning Skins. Fresh blood can be removed easily by washing the blood patch with warm water, of a temperature not above blood heat, in which is dissolved a little of Hudson's Extract of

Soap. If a bird is the subject, never allow the feathers to be wet longer than is absolutely necessary, and extract as much moisture as possible with a dry duster. Then saturate the feathers with benzoline, sprinkle plaster of Paris over them, beat the plaster off again at once, and repeat the process, using fresh plaster and adding more benzoline until the feathers appear dry.

Benzoline is a solvent of grease; it also forces out the water contained in the feathers and prevents the plaster from setting, but quick beating is required when the first plaster is applied. The plaster absorbs the grease dissolved by the benzoline and also cleans the feathers, but the skins must be thoroughly beaten to get the plaster off. If the skin has no blood on it, the soap-powder and water will not be required, and much time will be saved. This recipe will also answer for the treatment of small and large animal skins.

The composition for stopping up and repairing holes is made by mixing melted glue and well ground whiting to the consistency of stiff dough; the amount of glue must be determined by testing the composition with the fingers. It should feel tacky and stick to the finger; if it crumbles, add more glue. When worked well together, add one tablespoonful of boiled oil for every pound of glue used, and knead the constituents until they are thoroughly mixed. The composition can be used after it has become cold and hard, by steaming it.

In fixing artificial eyes, modelling nostrils, lips, tongues, and the innumerable requirements of taxidermy, this composition is used. It can be made to imitate any surface by manipulating it properly, and is easily coloured.

Arsenical Soap. This is made of 3 lb. white curd soap, 3 lb. arsenic powder, and 8 oz. camphor. Slice up the soap and melt over a fire in as much water as will just cover it, and stir well to keep it from burning. Crush the camphor very small, with a little methylated spirit, and add this together with the arsenic powder. The whole should form a creamy paste. Arsenical soap has been decried by some taxidermists, but it still holds its place with the trade, and will do so until a better preservative is found.

Treatment of Skins for Storing. Animal skins are sometimes found infested with a pernicious insect (*Derm·s'es*), the grub of a small beetle. It is the most destructive insect with which the taxidermist has to contend. It eats through the toughest skins, and it has been known to eat through cork. When this pest is found in any specimen, instantly saturate everything in the same case or box with turpentine, and keep the case closed for a short time.

Naphthalene crystals are very good to use in boxes of specimens of all kinds. Cyanide of potassium is a dangerous poison, but a powerful insecticide if placed in boxes of skins; it should be enclosed in a block of plaster of Paris, the cyanide being placed in the plaster before it has quite set. If it is not enclosed in plaster, the chemical will absorb moisture, and run on to the skins with which it is in contact and spoil them.

Natural history specimens should be stored in a very dry place, as dampness will induce the attacks of insects. A periodical overhauling is essential; brushing the skins and exposing them to the sun for a few hours is a good plan.

Cabinets of insects are subject to the attack of a mite which eats the tissues of the body, causing the wings and legs to fall off. The presence of this pest may be noted by the dust which surrounds the insect affected. The best remedy is benzoline, or petrol will also do. Run the spirit into the drawers until all the contents are saturated; close up the cabinet and allow the spirit slowly to evaporate; it will not leave a stain. Be careful in using this spirit, as it is very explosive; keep all naked flames from contact.

If cases containing stuffed birds and animals are found to have moths inside, which sometimes happens in old cases that have become damaged, a saturation with petrol will stop the ravages of the insects, and kill the grubs, but the specimens will have to be watched, as the spirit will not affect the eggs of the insects, which may still exist and hatch in a week or two.

Hints for Big-game Hunters. In most instances the actual skinning of big game is done by natives, but the sportsman who values his trophies will find it pay to supervise the work, and see that due precautions are taken to preserve the specimens, as their enemies in the tropical regions are more numerous.

Reducing the baggage to a minimum is a consideration, but the hunter should on no account proceed without a good supply of powdered alum, which must be stored in conveniently sized tins (a lion's skin requires about 3 lb. of alum to cure it).

When an animal has been skinned, and all surplus fat and flesh have been cleaned off the skin, it should be well rubbed with alum, and then should be rolled up to allow the alum to dissolve and penetrate the skin.

The action of alum is astringent; it shrinks the skin and thereby keeps the hair firm. Great attention must be paid to the eyelids, nose, mouth, and ears, to get them well saturated with alum.

After about eight hours, the alum having done its work, the skin should be pegged out flat, flesh side upwards, *in the shade*. On no acount should a skin be allowed to dry in the sun, as this will burn it, making it brittle and quite useless for any purpose. If, by any accident, alum is not available, dry wood-ashes are a good substitute.

Horns, trophies, and skulls should have all flesh removed, and if time permits may be placed inside an ant-hill. These insects will rapidly eat away all vestiges of gristle and flesh, leaving the bone as clean as if it had been boiled. The skins should be hung in a situation where ants cannot reach them, or much damage will result.

On reaching the coast all skins and trophies should be overhauled before being packed for shipment, and saturated with crude turpentine. This will ensure their safety during the voyage home. Many valuable specimens have been irretrievably damaged through neglecting this simple prevention, the insect pests having been packed up with the skins, and completing their work of destruction undisturbed in the packing-cases.

TOBACCONISTS

The annual licence to sell tobacco by retail costs but the modest sum of 5s. 3d. The trade itself, as often conducted, demands no great skill or experience, and it is but natural that many people without either should turn to this trade as a means of livelihood, or of ekeing out the profits of another business, such as that of a hairdresser, grocer, newsvendor, confectioner, or publican. The publican's tobacco licence is held for the same period as his spirit licence; when held apart from such a licence, that to sell tobacco and snuff is

renewable in July each year. It is unnecessary, perhaps, to point out that while the trade is so easy of entrance that even young women and widows practise it, this very fact exposes the beginner to all the more competition. Moreover, in most towns very smart shops are now run by companies and firms which have reduced the business of retailing, and certainly their window-dressing, to a fine art.

Starting Business. Since some tobacco-shops are the smallest of all shops, while others are among the most brilliant and imposing, there is obviously a very wide range of choice. The kind of shop, however, will depend greatly on the neighbourhood and the class of customers likely to frequent it. Costly fancy goods and high-priced cigars and pipes, which are the most remunerative portions of a high-class tobacconist's stock, would be quite out of place in a shop where the customers are likely to belong solely to the artisan class. Having selected his "pitch," the intending tobacconist will probably lose little time in studying the advertisements of the trade papers, and he will therein discover the existence, both in London and the provinces, of obliging firms who will supply him with "mixed parcels" of goods at almost any figure he cares to name. Of "proprietary" goods there is a bewildering variety from which to select; it would be well to try to learn the tastes of the expected patrons as far as possible before buying any large stock.

The Shop. In a tobacconist's shop the window is of primary importance. Most of the up-to-date windows are of plate-glass and occupy the whole front of the facia. To facilitate dressing, the whole window-fitting is sometimes removable, or made to revolve. Plush-covered shelving is much used for the attractive display of pipes, cigar-holders, silver goods, etc.; and mirrors at the back and sides usually assist the effect greatly. The beginner will find it worth while to pay a visit to London or one of the larger towns in order to inspect specially the tobacconists' windows and their arrangements.

Much depends on a bright window display; the duller the neighbourhood, the greater the contrast and the effect thereby gained. In dressing the window it is well, if possible, to show loose tobacco. For cigars and cigarettes, dummy boxes or packets can often be used to save the deterioration of stock. For the interior of the shop a few medium-sized shelves will be useful, and have in the counter some good-sized drawers. For storing tobacco a light, well-ventilated, and dry cellar is desirable, the leaf being kept in wooden casks or glazed earthenware jars with loose tin lids. In the shop the tobacco most in demand may be placed in the counter drawers, which, if not of hard wood well planed, should be lined with zinc.

Cigars require different treatment and a higher temperature. If the shop itself is fairly well heated they may be placed on the upper shelves; but at the seaside a proper stock-room, however small, will be needed to save them from the destructive effects of the salt, humid air. Such a room should have, if possible, boarded walls, not damp and clammy stone; and artificial heat may be provided by steam pipes or by a siphon gas-stove consuming its own fumes. Where a room is not available, a suitable stock-room of small dimensions may sometimes be partitioned off at the back of the shop.

Treatment of Stock. With cigars the great thing for the retailer's attention is their proper "conditioning"; with tobacco, the avoidance of mildew. Both these depend on proper storage. British cigars, of which an ordinary stock will comprise perhaps 75 per cent., are seldom sent out "conditioned" by the manufacturers, though the wholesaler may complete the process before the cigars reach the retailer. To condition them, cigars, after leaving the factory, have to be subjected for several weeks to a temperature not less than 60° or more than 80° F. Though the outer wrapper may seem dry and may crackle when pressed between the fingers, and though the ends may be brittle—the signs of a conditioned cigar—the "filler" inside may still be sappy and damp. Even a bad cigar may be improved by conditioning. For this process, steam-heat is the best. To allow the cigar moisture to evaporate under the heat, it is well to prise open the lids of the cigar-boxes a little, or else to bore in the boxes a few gimlet-holes, taking care, of course, not to injure the cigars. The great importers of Havana cigars keep them in London in a constant temperature of about 65°. Speaking of Havanas (spelt Habana in Spanish), it may be mentioned that the colour-marks are as follow: "Claro," very light, very mild flavour; "Colorado claro," light and mild; "Colorado," brown medium; "Colorado maduro," dark brown and full flavour; "Maduro," dark and very full flavour.

Quality of Cigars. But it is said to be a mistake to suppose, as many smokers do, that the very light cigars are necessarily the mildest. The properly matured leaf, which smokes milder, is also a little darker than the immature leaf, often used for wrappers on account of its light colour. When the plant is perfectly matured before cutting, the leaf, although there are light and dark shades of it, is generally of a rich brown colour; and experts aver that such wrappers, when properly worked, will have a sweet and mild taste, even the darkest colours. A retailer samples his cigars by smoking one taken from the second layer in a box, and also by running a sharp penknife down the centre of another to learn the character of the inner wrapper and the "filler." In the smoked cigar the ash is not an infallible sign, though a white ash is usually good (especially in the cheaper lines), and grey inferior; but whatever the colour there should be regular burning. The better class of cigars should have a dull, slate-coloured ash, and should crackle crisply when gently rolled along the palm of the hand.

Precautions against Mildew. With regard to tobacco, mould is a great enemy to the "rolls" and "cuts," and any leaf that is moist. When tobacco parcels are received they should be opened out and inspected without delay, and if not found satisfactory returned promptly to the manufacturer; if only a little heated, turning over and airing may be all that is necessary. The amount of moisture in the tobacco being strictly fixed by law, it may be presumed right in this respect when received from the manufacturer; and the retailer's problem is to keep it so, preventing loss to himself by evaporation and avoiding the opposite error of forbidden moisture. Evaporation may be prevented by covering all tobacco each night with a double thickness of canvas wetted on the upper side, the tobacco being turned over with the hands next morning; or if the tobacco gets too dry the outside may be sprayed with pure cold water applied by a diffuser such as is used for perfume, but care must

be taken against overdoing this. Tobacco kept in casks should be turned over and shaken occasionally to prevent its becoming sodden at the bottom and generating the heat which produces mildew.

The same advice applies to the earthenware jars. Every ten or twelve days or so, empty and inspect these receptacles, and note carefully whether any tiny white specks—the fungus of mildew—are scattered through the tobacco. Your jars should be carefully wiped out with a coarse cloth; and the empty casks—the contents may be temporarily placed on a sheet of brown-paper in the cellar—should be cleansed by a blaze of paper, followed by the application of the dry cloth. Roll, cake, etc., are less likely to become mildewed, olive oil being used in their manufacture; where any sign is found, a little Lucca oil should be applied with a soft brush. Note that the quantity of oil, like moisture, is strictly limited by the law. Cheap tobaccos, which "go off" quickly, are sometimes kept in galvanised iron buckets, which can be turned out and easily brushed clean every morning. Packets of tobacco, now so largely sold, should not be stored in a damp place; usually the shelves under the counter will serve for this purpose. For "smalls," which accumulate in weighing up, and so on, keep a special receptacle, and from time to time return the contents to the manufacturer, who will allow for them. Every retailer should endeavour as soon as possible to sell his own "mixtures." Businesses have been started on a capital of £25, but this is rather a small sum to begin with.

Pipes and Fancy Goods. In the selection of these the tobacconist should aim at showing a stock that will be representative and comprehensive of whatever his clients are likely to require, remembering that unsaleable stock, even though it may show a good profit, as these goods often do, is capital lying idle. Without going into detail, we cannot do better than recommend the beginner to study the catalogues and lists of special assorted parcels that are sent out by various sundriesmen in the trade. In these lists will be found full information also as to terms and discounts.

Side-lines. The side-lines most commonly run in connection with the tobacconist's business are walking-sticks—which often pay very well, especially in seaside or other tourist towns—news-agency, hairdressing, stationery, cutlery, fancy china, leather goods, etc. It is necessary to bear in mind that when heavily plated articles are sold, a plate-dealer's licence may be required. For gold above 2 dwt. and under 2 oz., or silver above 5 dwt. and under 30 oz., a licence costs £2 6s. Expensive sticks and the better class of cigar and cigarette cases, etc., may come under this head, but it is just these high-priced goods that, as a rule, return the retailer his highest profit.

Legal Notes. Mention has been made of the restrictions imposed by the law upon the quantity of water and oil permitted in tobacco. Another point to be remembered is that "Cavendish" or "Negro-head" tobacco, which has to be manufactured in bond, is supplied to the retailer in packets bearing the Government stamp, and this stamp has always to be obliterated when the packet is sold. Care must be taken, however, not to break the packet until it is sold, as this is not permitted by the Excise regulations. Note that the Excise officers have the right to enter and inspect the contents of any place licensed for the sale of tobacco; and if adulterated tobacco is found on the premises, or if any tobacco or snuff is wilfully concealed, the tobacconist renders himself liable to a penalty of £200 and forfeiture of the goods.

TOY MERCHANTS

The retailing of toys and games may be divided into two classes. In the one case the stock would comprise inexpensive articles, and would not cost a great deal to purchase; in the other, the department would include outdoor games and expensive indoor apparatus, such as billiard-tables, bagatelle-boards, phonographs, lanterns for enlarging, cameras, and, indeed, all the paraphernalia which are required for recreation and sport. The first class affords a capital opportunity for ladies desirous of starting in business; the second would require the superintendence of someone with expert knowledge of the rules which govern golf, tennis, cricket, football, billiards, and the rest. Indeed, from £300 to £500 might easily be sunk in this class of stock, which is listed at prices carrying a range of discounts from 15 per cent. in the case of billiard-tables, to as much as a third in the matter of tennis-rackets, cricket-bats, etc. Moreover, this side of the business requires rather large premises, or at least a good shop-front, and a light, open showroom behind. It cannot be conducted without a moderate amount of local advertising; and even if the proprietor is in quite a small way, the salary of at least one assistant would have to be met, unless the proprietor lives on the premises and is prepared to be tied to the place during business hours. Thus, assuming a sporting games stock of £500 can be turned over three times in a year, and taking the average discount at 25 per cent., the gross profits would be between £350 and £400, out of which all expenses, including rent and rates, would have to be met before the proprietor began to take his profits. It will be seen, then, that a young man with a small sum to invest will find in this business an opening which will return him a moderate income. Of course, a £1500 return is by no means the limit possible, especially if in time the proprietor can add cycles or sporting games, or both.

Our immediate concern, however, is with toys, in the more generally accepted definition of the word. This, as has already been pointed out, is a business which appeals to women. It can be carried on in comparatively inexpensive premises; a hundred pounds' worth of stock goes a long way towards making a brave show, and success does not depend upon a large population. There are children everywhere, and therefore customers.

Stock. The stock to fill a shop of good class, such as we have in mind, would not cost much more than £100. Practically the whole of it would be purchased at prices which represent from 25 per cent. to 33⅓ per cent. off the selling price. It would be subdivided into a variety of sections, appealing to different ages. First, there would be toys to retail at from 1d. to 6d., the kind of things that we associate with Christmas-trees at year-end parties. Penny toys cost from 7s. 6d. to 8s. 6d. per gross; toy-picture-books, 2s., 2s. 8d., 4s., or 8s. a dozen, as they are intended to sell at 3d., 4d., 6d., or 1s. respectively. Dolls, for which there is a steady sale, carry similar profits, at from a penny apiece upwards.

For older boys and girls every season brings with it a fresh batch of games for the table. Outdoor sports in miniature, which are not always successful copies of the original, sell freely at all times, including table bowls, croquet, etc. Besides, there are old-established favourites for the table, such as

Halma, draughts, race games, Ludo, not to mention chess and backgammon.

Cards and Card Games. For all ages there are cards, comprising bridge, whist, bézique, Patience, etc., which are sold under a Government stamp, and dozens of others, including Snap, Happy Families, and other old-fashioned games which refuse to be counted out of date. Besides, a number of new ones, some of them of American origin, have sold freely in recent years. Most of these are sold in various editions, costing from 6d. to 3s. per pack or set, which prices also carry a discount of from a quarter to one-third.

Mechanical Toys. These are splendid sellers; and if a group are arranged to run in a window during business hours, a crowd is always to be found round the retailer's shop-front. The variety of mechanical toys is remarkable, and behind all those which have been mentioned are trams and rolling stock, operated by clockwork, steam, and even the electric current on the three-rail plan of the District Railway. In this department, again, discounts run ordinarily to a third.

Salesmanship and Buying. Selling toys requires patience and a pleasing manner. Children are not attracted by the typical business face and bearing. They not unreasonably and quite unconsciously assume that selling toys is an interesting as buying them, and success comes only to those retailers who can win the goodwill of the little folk. Sixpence to many a child is a little fortune, and not to be spent without first weighing the relative merits of many articles. Even parents are difficult to please in this matter, with the result that what appears to be a simple matter is really one calling for no little tact and courteous attention.

Buying, of course, calls for care, and a due recognition of local circumstances and the seasons. In most big centres there are large warehouses where novelties can be seen and stock selected. The chief of these are to be found in Houndsditch, in London. A visit to these centres twice a year will afford better opportunities of replenishing stock than haphazard purchasing from travellers or by post from catalogues, in which the descriptions of the stock are ordinarily more artistically adorned than accurate.

UNDERTAKERS

Generally speaking, the duties of an undertaker are to measure the dead body, to make the coffin, to arrange with the cemetery authorities, to provide the carriages and men, and to accompany the funeral to the grave. There are funeral furnishers, however, who do not come directly into contact with the mourners. They may be wholesale manufacturers or jobmasters, providing the undertakers with coffins, carriages, and all the appurtenances. In most cases the undertaker, however, makes and furnishes the coffin, and applies to a known carriage-master for hearse and fittings.

The Shop and the Workshop. Having a bank balance of at least £200, the young man —he should be at least 26 to 30 years of age— would look around for a suitable site to begin operations. First of all, he would endeavour to secure a roomy, well-lighted workshop, preferably with an adjoining sale-shop fronting the main street. Perhaps this will not be easily secured, and, if so, separate establishments within easy distance of each other would be selected. In any case the workshop must be dry and well lit, in a good locality, and with convenient access. Plenty of light is required for the work; even black stuff is "sore on the eyes." Such a workshop would cost £10 to £20 rental (or more if in London), and it would be divided into two portions. One part would be wood-lined, and fitted with shelves for the finished shells, for cloths, linings, or general ironmongery, all of which must be kept dry. The other division would be used as the workshop proper. It would contain one or two small benches with vices (costing £4 for two), half a dozen trestles for use in the shop, and the same number for use at funerals (£2); and, where possible, a small electric motor and a small saw-table. A motor (one horse-power) would cost about £14, a saw-table £12, and shelving about £5. The sale-shop should be divided into a front apartment for callers, and a private room behind. In the front shop there had better be a small counter, a desk, and a few chairs, shelving round the walls, and a few drawers. On the shelves there would be displayed wreaths, flowers, brass mountings, or anything else that could be exhibited. The drawers are for funeral stationery, and a selection of grave-cloths, shrouds, and linings. The private room at the back should be fitted with a writing-table, chairs, and the usual office furniture. The fittings of the front shop and private room, including floors covered with floorcloth or linoleum, should not cost more than £20 all told, and the rent of both shops in conjunction would probably be £40 to £60 per annum, according to locality.

The Stock. As in most businesses, there are wholesale factors or manufacturers of the various articles required for the trade. There are manufacturers of all kinds of wreaths (artificial and natural), coffin furniture, special wood, mouldings, etc., of coffins, besides cloth, linings, and so forth. With regard to wreaths, it is often advisable for the beginner to have an arrangement with a local wholesale florist, but, failing that, there are many regular wreath factors in the trade ready to supply all kinds of mementos on demand. For an opening stock, four marble wreaths, with stands, of assorted kinds, would be necessary. These would cost about £8 15s. Then six enamel wreaths would be ordered, at a cost of about £1 16s., and one dozen preserved flower wreaths (18s.). A suitable selection of inscription glasses, vases, and graveside decorations could be obtained for £1. In stationery, funeral cards (such as are given to cord-holders and pall-bearers) would cost about 12s., while ordinary office stationery and books would absorb another £2 10s. That is all the stock necessary for the sale-shop. For the workshop the stock would include 1 doz. assorted deals of oak, ash, and elm, cut to ¾ in. thickness (£5 8s.); 300 ft. of suitable mouldings (£1 5s.); 1 doz. deals of third quality yellow pine, red pine, or white pine (£3 6s.), and 40 yds. of lining for bottoms (£1 13s.). These would all be stacked, dried, and used as required. Then in cloths for covering or lining coffins, etc., there would be obtained one piece each of black (£2 5s.), white cotton (15s.), and embossed (£1 3s. 4d.), and half a piece of velveteen (£2 6s.). The black cloth is in 45-yd. lengths, the white and the embossed in 40-yd. pieces, and the velveteen in 30 yd. Besides these, there would be 2 doz. side-sheets (for placing up the sides of the coffin and folding over the body), one quality costing 10s. 6d. per doz., the other 7s. 6d.; ½ doz. embossed sheets (9s.), and four sets of best sheets (18s. 6d.). Frillings would cost at least 9s.; six shrouds would be 16s., and 1 doz. assorted grave-gowns £1 10s., while six sets of silk cords (£1 2s.) and 2 doz. sets of assorted cheaper quality cords

would mean another sovereign. One piece of waterproof sheeting, which is often used in place of zinc lining, would cost from 40s. to 48s. In ironmongery, two sets of brass mountings at £2 10s., two sets costing £2, four sets costing £2, and four sets costing £1 2s. would give a very fair selection. These might be assorted brassed and nickel-plated. A "set" includes one name-plate, side-plates, and handles for cords; and where black coffins are used it will be necessary to have black or white mountings and lace. In such cases, four sets of black and four sets of white, for adults (3s. per set), and six sets for children (1s. 6d. per set), would suffice. Another 15s. would be spent on the ordinary nails and screws.

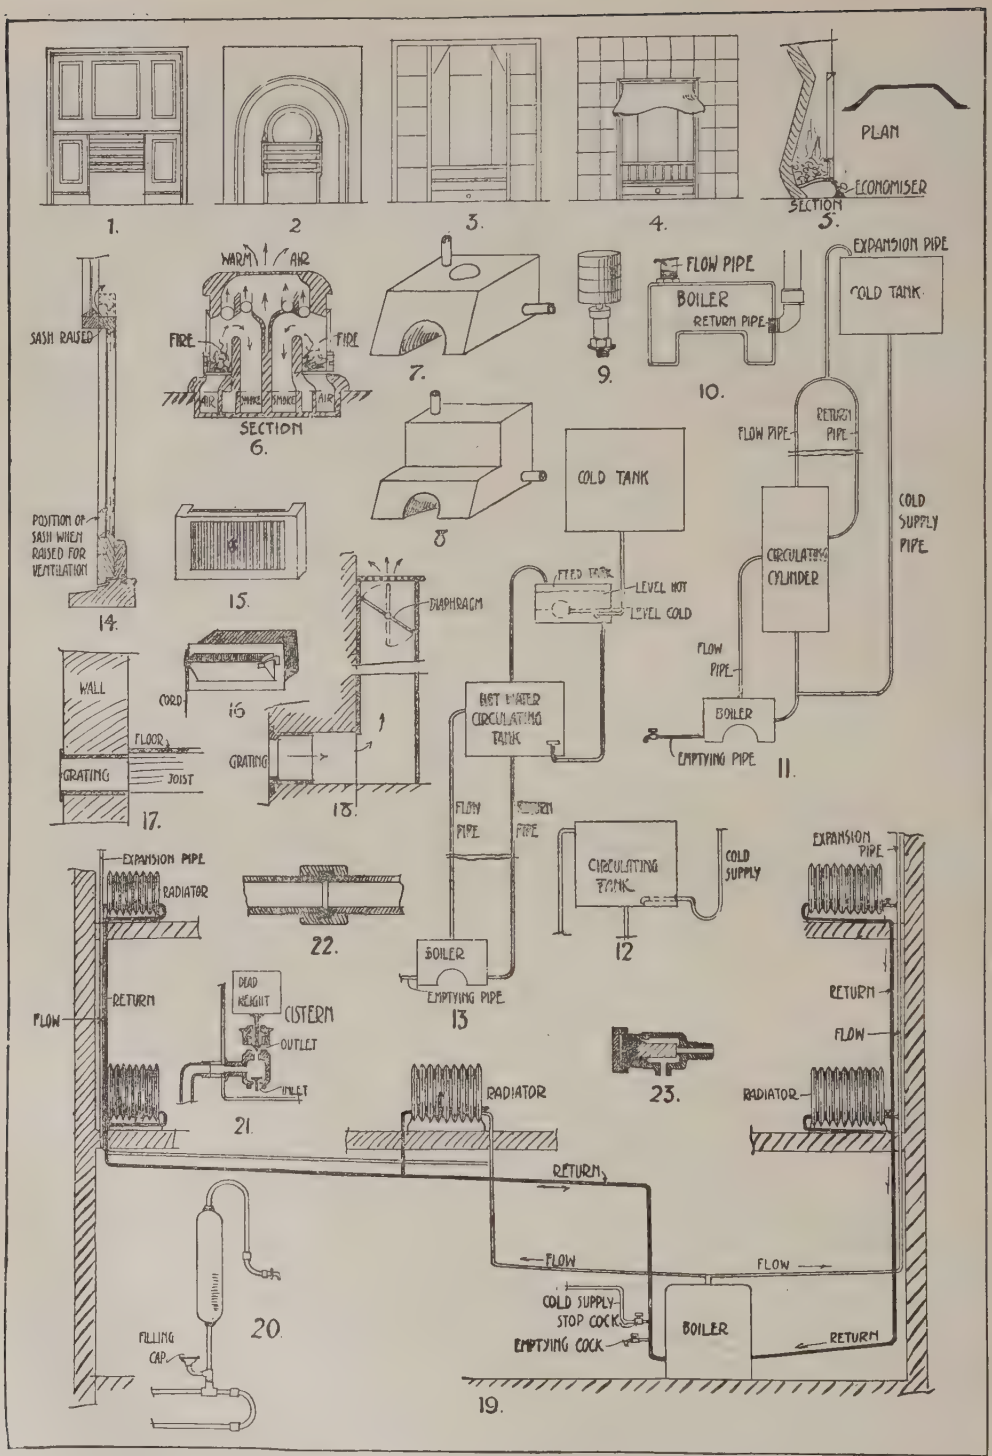
The Method of Procedure. When the relatives of the dead call, they should be ushered into the private room, where all particulars must be noted in a book kept for the purpose. These include the name and address of the person giving the order (for he or she is responsible in law for payment), the name, age, and occupation of deceased, the cause and date of death, the name of the doctor who attended at the death, particulars of the burial ground, if any, when the coffining or "chesting" is to be done, the hour and day of the funeral, the service desired, the style, quality, and price of coffin, and other questions regarding local customs or particular desires about which you may not be sure. In measuring the body, one must take the exact length, width at the widest, and the depth. The coffin should be made inside at least 2 in. longer and 1 in. deeper than the actual measurements. The finished coffin should be delivered punctually at the time appointed. With regard to screwing down the lid, local custom and the wishes of the relatives have usually to decide. The funeral arrangements differ in many localities, and it is the business of the undertaker to learn local customs. In lifting out or in, in public, the coffin must be always carried feet foremost.

The Question of Prices. Prices are affected by many things—wages, rents, facilities, and the character of the opposition. They should be neither too high nor too low, but commensurate with a good class of business. The ordinary charge for an adult coffin averages about £3, but for customers in a poorer station of life a lower charge should be made, without loss of profit, by reducing the quantity and quality of the materials and furnishings. Varnished pine coffins of better qualities and richer mountings average about £4 4s.; plain oak or elm, £8 or £9 if polished, and higher prices for the best quality and superior finish. Where cords and tassels with brass side-plates are used, 15s. to 25s. would have to be added, and often the coffin requires a zinc lining, which would increase the price by about 12s. 6d., or, if soldered down, by about 20s. Attendance at an ordinary funeral is generally reckoned at £1; but where coffins are lined, extra assistance is required, and the charge would then be 30s. When country journeys or travel by train are undertaken, the charge is usually 10s. per man and £1 for the undertaker himself, plus all outlays. Carriage by rail for a corpse is 1s. per mile, but an empty coffin is carried at the usual parcel rate. For undertakings to long distances hires may be wanted at both ends, and this increases the expense. The cost of hires will vary according to the style of funeral carriage and the horses. A plain hearse should run from 8s. to 10s. upwards per funeral, a pair-horse carriage from 21s. to 30s., or more. Single carriages for the mourners are usually hired at from 5s. to 7s. 6d. each, and pair-horse carriages from 15s. to 21s., according to style.

Profits and Credits. The safe plan is to have a regulation scale of prices for coffins, which will include ordinary attendance, then add hires (from which a small commission is received) and out-of-pocket expenses. For an ordinary undertaking a clear profit of not less than 25 per cent. should be received. For such as call for a good class of oak coffin, with more stylish work, proportionately higher charges are made and greater profits accrue. The usual credit given by the wholesale trade is one month, with 2½ per cent. discount. The undertaker should insist on doing a cash trade, for it is easier to get the money during the first flush of grief than later on, when the fountains have dried up somewhat. If there is any suspicion of pecuniary insecurity, a surety or a deposit should be insisted upon, and no discounts should be given.

Cremation. There are several crematoriums in various parts of the country, the principal being in the neighbourhood of London. Woking and Golder's Green are, perhaps, the best-known places, and the proceedings are under the direction of the Cremation Society. When a wish for cremation is expressed, application in writing must first be made to the company by the executors or nearest relatives of the deceased (unless the deceased has already communicated such a desire during his or her lifetime), stating that it was the wish of the deceased to be cremated, or that he, or she, entertained no objection thereto. Upon receipt of instructions, regulation application forms are sent by the Society, which are filled up and sent to the undertaker, who makes all the necessary arrangements. Two certificates from medical men (one of whom must have attended the deceased), stating the cause of death, are required, and the names and addresses of such medical men should be given in full. The Cremation Society reserve the right of refusing to carry out a cremation without assigning any reason. Cremations may take place two days after receipt of application form. The registrar's certificate is required, as in ordinary burials, and it is imperative that it be sent to the undertaker without delay, as the Society requires its production before the order for cremation can be issued. A pine shell, covered or polished, is sufficient to carry the body. Cremation being considered only a process preparatory to interment, the Bishops of the Church of England have ordained that the Burial Service, which includes the committal of the body to the grave, should not be read until the ashes are brought to the churchyard for interment. This does not, however, preclude a service being held in the chapel, if desired, prior to cremation. The fee to the local clergyman, if retained, would be £1 1s. The fee for cremation is usually £5 5s., alike for adults and for children.

As a guide to cost, one might assume a cremation at Woking from London. There would be conveyance of the body from any metropolitan station to Waterloo, with hearse and men, railway charges to Woking, hearse and pair from Woking to crematorium, attendant from London, cremation fees, making necessary arrangements with Cremation Society, supplying casket and brass plate; in all, about £15 10s. for net cash. In estimating, the undertaker would add charges for his personal expenses, and would leave a margin for any telegrams or incidental outlays that might be necessary.



1–23. HEATING AND VENTILATING APPARATUS

1. Heating Installations. Natural and Artificial Ventilation. Dr. Hill's Experiment. The Hot-Water System. Lighting Systems.

HEATING, VENTILATING & LIGHTING

Some means of artificially raising the temperature of living-rooms during at least part of the year is essential in this and in many countries; and, apart from this, it is necessary to provide for the means of cooking food and heating water for domestic use. These requirements may be met in a variety of ways, depending to a considerable extent upon custom, but varying with the circumstances of the building to be dealt with.

In ordinary dwellings in this country the open fire is the usual method of warming rooms. The general improvement in hot-water heating, however, has brought central heating on this system into very general use, and it is unusual to find a new house of any size that has not such a system installed. Moreover, an indication has shown itself during the last few years that there will be a demand for low-pressure hot-water heating apparatus in the small, £30 to £40 a year houses which are so numerous in the large towns and cities of England. There are certainly many such already in existence. At the same time it does not appear probable that any form of heating apparatus will quite supplant the open fire, which has several features of particular merit, some of which have not long been recognised.

The Problem of Heating. Perhaps the best means of bringing to light the advantages and disadvantages of the various methods of heating and ventilating is to consider in some detail the problem to be solved.

No one can deny that a man who spends his life in the open has the best chance of keeping himself in perfect health. A very great number of the illnesses to which we are subject are known to doctors as "indoor diseases." The problem we have to solve, then, is to keep the air conditions inside our dwelling as nearly as possible like that outside. As, however, those who pass their time indoors are generally occupied at some task or amusement which debars them for the time from exercise of any kind, we are confronted with the added difficulty of maintaining the internal condition of our dwellings as nearly as possible like the outside conditions in summer time, when we can sit out of doors in perfect comfort.

We get an insight into the external conditions by regarding the temperatures in the sun and in shade. The sun temperature is always several degrees above the shade temperature. The latter is, of course, the air temperature, while the former is the temperature of the radiant heat of the sun. A difference in air temperature and radiant temperature, then, is one of the essential features for which we should strive within our dwellings.

Out of doors, again, there is nearly always air moving, and this has recently been shown by Dr. Leonard Hill, Professor of Physiology at London Hospital, to be a matter of vital importance.

The humidity of the air is another important feature. Out of doors we get a constant variation, but in Nature it is always preserved within limits that are suitable to health. Air automatically takes up and deposits moisture with every change of temperature. In our country, surrounded as it is by the sea, we never experience anything out of doors approaching the dryness of desert air. It will be shown, however, that within doors this is by no means unusual. Again, in a crowded room which is improperly ventilated it is a very common thing to find air absolutely saturated, and this air, moreover, clings around the occupants in the part of the room where it does most harm.

Dr. Hill's Experiment. Dr. Hill has shown this by an experiment which is so significant and interesting that it is important to describe it. He has had made a small air-tight chamber, with one glass wall intended to permit careful observations from the outside. The chamber measures three cubic metres. Into this small space he crowded eight or nine students, and hermetically sealed them in.

It is easy to imagine what happened. The students who were imprisoned soon lost the jovial humour in which they entered on their task, and it was clear within a quarter of an hour that the conditions were becoming uncomfortable. The thermometer inside the chamber was seen to be quickly rising, and an analysis of the air showed an increase of CO_2 (carbon dioxide). This was, of course, due to the respiration of those inside, oxygen being used up in the process of breathing and CO_2 being given out. This is a product of the combustion which is always going on in our bodies. The quantity of aqueous vapour in the air also increased.

Dr. Hill had an instrument for measuring the volume of the air which each man inhaled at each inspiration. It showed a continual increase during the course of the experiment. The rate of breathing also increased. At the end of half an hour the men were showing signs of acute distress. The temperature by this time was more than 80° F. Their heart-beat had become very rapid. They were suffused with perspiration, which could not evaporate, because the air had become saturated, and each man's temperature had risen above the normal. Very careful observation was, of course, kept to note if the condition of any of the men became critical, for it must be remembered that they were being slowly suffocated.

At last a point was reached beyond which it was not deemed safe to go, and then two small electric fans, which were fixed in a horizontal position just below the ceiling of the chamber, were switched on. These fans were not connected to the outside. The only result of their motion was to set up a current of air inside the chamber. The immediate effect of that air movement was wonderful. The students thought that a current of fresh air was being introduced from the outside. Immediately they revived. One of them afterwards described his sensations, and said it was like coming out of an oven without any air in it, and passing on to a headland by the sea on a bright, fresh day. All the men were examined medically, both before and afterwards, and were pronounced to be none the worse for their experience.

Deductions from the Experiment. The experiment is remarkable, because it brings to light entirely new features in the ventilating question, and also shows us that some of the formerly accepted principles are valueless. Perhaps the most important is the fact that what was formerly spoken of as the chemical impurity of the air, measured by the amount of CO_2 present in it, is of very little importance. As long as the added CO_2 is evenly distributed throughout the entire room, it does practically no harm at all. As it can be evenly distributed with air movement, it accentuates the importance of this movement, which, it will be remembered, is one of the conditions prevailing out of doors.

Incidentally, it also shows that the vast volume of air which under the old rule was considered necessary to keep the CO_2 in the air down to 6 parts per 1000 (the figure which was arbitrarily fixed as the point of maximum impurity for air in buildings) can be very greatly modified.

The Effect of Stuffy Rooms. The real cause of the acute suffering to which the students were subjected before the fan was set in motion was the clinging film of hot, moist air which occupied the space in which they were compelled to breathe. This caused the rise in bodily temperature, because the protective mechanism with which we are provided for counteracting the tendency of our normal temperature rising was put out of action by the moisture surrounding them. This mechanism, one of many found in the human body, is interesting. When our temperature begins to rise on account of any external cause, the blood stream is diverted from the internal organs of the body, and flows through the system of veins which lie just beneath the skin. This produces moisture on the skin, which we know as perspiration. The cooling effect is brought about by the evaporation of this moisture. In the case we are considering, the blood performed its part of the function and produced the moisture; but on account of the condition of the warm, saturated air immediately surrounding the students, the evaporation could not take place, and thus no cooling effect was produced. In the same way, and under the same conditions, the blood stream flushes the respiratory tract, which exudes mucus.

That these phenomena do occur has been very satisfactorily proved; and if confirmation is needed we only have to remember the flushed faces of those who have spent some time in a hot, stuffy room. An examination of the throat also shows that the pale pink colour which is characteristic of the normal condition has been changed to a bright red colour. The risk of catching a cold, to which one is subject on going out into the cool air after leaving a hot room, we all well know, and the condition of the mucous membrane which surrounds the respiratory tract fully accounts for it.

The deep and rapid breathing of the students was certainly uncomfortable but not harmful. It was an involuntary effort to obtain the necessary amount of oxygen from a mixture which had been considerably depleted of that gas, and had in consequence to be delivered into the lungs in larger volume in a given time.

It must not, of course, be assumed that there was no danger in the experiment, for undoubtedly there was. The glass wall of the chamber was provided in order that it might be seen when the condition of the students approached a critical stage. Had the fan not been started, the temperature of those inside would no doubt have risen to a dangerous extent, and the air would in time have been so depleted of oxygen that the effort of drawing in a sufficient quantity to get the necessary amount of oxygen to sustain life would have been too great.

The value of the experiment lies in the fact that it showed that by circulating the air it was found that there was still sufficient to sustain life in comfort, in spite of the extreme smallness of the chamber, and also that it brought to light the importance of keeping the amount of moisture within reasonable limits, and of that air movement which is now known to be so essential to health.

Essentials of Ventilating and Heating Systems. The chief points, then, which we must endeavour to reproduce indoors when we undertake the warming and ventilation of our houses are as follow:

We must have a source from which heat is radiated, and the temperature of this radiant heat may be considerable. The intensity varies inversely as the distance, so we can move away if it is too intense.

We must have moving air.

The temperature of the air should be about 60° F. If it is lower, there is a chance that we shall feel chilly when sitting down.

If the room is not a crowded one, the humidity may be anything from 70 per cent. to 100 per cent. When we are sitting still in a temperature of 60° we do not perspire much, and this is an indication that there is no tendency for our normal temperature to rise. The humidity should not be allowed to fall much below 70 per cent. In other words, the air should not be allowed to get too dry. If it does, it greedily evaporates moisture, and even the moderate amount of perspiration which normally covers the skin is quickly taken up, and this produces a chilling effect.

It is essential that a moderate air change shall take place, but certainly it need not be so great as we formerly considered necessary.

With these points before us we can more readily appreciate the advantages and disadvantages of the various means of heating and ventilating which are in common use.

The Open Fire. A heated body gives out its heat by radiation, conduction, and convection. [See PHYSICS, page 1403.] The commonest form of house-heating is the open fire, which is an example of radiant heat. All forms of grates are liable to the objection that the fuel burnt in them is wastefully employed, much of the heat passing away with the products of combustion, but some forms of grates are much more wasteful than others. The old-fashioned forms known as the *hob-grate* [1] and the *register stove* [2], of which there were many varieties, were extremely extravagant. In both, the receptacle for the fire was raised high above the hearth, and had vertical or horizontal bars in front and horizontal fire bars below; the air had free access not only to the front and upper surfaces of the fire, but to its under surface, and was drawn up through the fire, and resulted in rapid combustion of the fuel. Such stoves were usually mainly of iron, often with the addition of thin firebrick backs and cheeks.

Modern grates are mostly constructed so that the fire is either close to, or actually on, the hearth [3 and 4], and when slightly raised a movable front, termed an *economiser* [5], is provided, so as to close the opening entirely after the fire has been lighted and is burning briskly. Though varying somewhat in detail, most modern fires have the back and sides of thick fireclay, generally about 2 in. thick, and

the sides are usually placed not square but on a splayed line, while the back is sloped forward over the fire [5]. The object sought to be secured by this form is to make the utmost use of the fuel, which directly heats the back and sides, and these in turn radiate the heat into the room, and, being thick, retain a considerable amount of heat after the fire has died down. All such modern grates are more efficient and economical than the old ones. Some of them have no ironwork at all except the bottom bars. Such grates were first introduced by Dr. Teale. The fire in them is sunk below the level of the hearth, which is raised above the floor level, and access for air is arranged under it by means of an opening which can be closed after the fire is once lighted. The *interior*, as it is termed, in which the fire is lighted, is of firebrick in one or two pieces, and the front may be formed of glazed bricks.

Other fireplaces are formed with but little more ironwork. A metal frame is attached to the front of the interior, which includes the front bars to the fire, and this form is well adapted for use with tiled jambs and top. These are finished behind the metal frame, which may be ornamental in form, and often includes an ornamental canopy, fixed or movable. Iron, brass, copper, and armour steel are used in this work, either alone or in combination, and around the opening there is added an ornamental mantel, and perhaps an overmantel, which is a purely decorative feature and is regulated by taste and means.

The advantages of the open fire at once become clear. It approaches more nearly to the actual outside conditions. We have the source of radiant heat and the moving air at a lower temperature, but it is just at this point that one of its disadvantages is apparent. The air which finds its way into a room, in winter is often so cold that it is felt as a definite and chilling draught. The other great disadvantage is the waste of fuel that is inevitable. It is questionable if the most improved grate has an efficiency of 20 per cent.; and it would come as a shock to a prudent man if he realised that he was wasting £80 out of every £100 he spent in coal.

Ventilating Grates. This form of open fire has a feature which is in one respect an improvement on the ordinary open fire. It warms the air which is drawn in to supply the demand for oxygen of the burning fuel, and so does away with the cold draught. This is effected by forming behind the firebox, or interior, a chamber surrounding the back of the fire, into which the air is admitted cold from outside, and from which it may be discharged, after it has passed round the grate and has become warmed, into the room. Such a grate may be formed with an iron frame having projecting gills at the back, which increase the radiating surface and assist in warming the air.

This class of grate is not very extensively used. The objection to it is that it is generally so constructed that it overheats the air supply, depletes it of oxgyen, and greatly reduces its humidity. Saturated air—that is, air containing as much moisture as is possible—if raised from 40° F. to 60° F., only holds in suspension half the moisture it is capable of holding, and so is reduced to 50 per cent. saturation, which, as pointed out, is *too* low. These limits, which are excessive, are greatly exceeded in ventilating grates. In warming the air supply it brings into operation the third method of heat distribution—namely, convection. This increases the efficiency of a ventilating grate to a higher percentage than that of the ordinary open fire.

Stoves. Heating by stoves is not much in favour in this country, although it has one great advantage: in the stove the furnace is entirely enclosed, and this gives a greater control over the rate of combustion. By checking this, and by using a hard coal, such as anthracite, it is possible to keep the fire always alight. This is a very important point. With the ordinary open fire, we heat up a room when we light the fire, and allow it to cool again when the fire goes out, which it always does during the night. The consequence is that we are always confronted with the daily task of warming up our rooms, which means a large expenditure of fuel before any heating effect is noticeable. With the stove it is possible to start the day with the rooms comfortably warmed.

Ventilating Stoves. Ventilating stoves are sometimes made, and are provided with air chambers and flues, so as to deliver warmed air into the room, as in the case of a ventilating grate. For hospital use a special form of stove has been designed, consisting, in fact, of two open fires placed back to back, so as to stand in the middle of a ward, with chambers and outlets for warmed air [6]. From such a stove an ordinary chimney is not usually taken, as it would occupy the centre of the ward, but a flue is taken down to the floor level, then horizontally in the thickness of the floor to one of the side walls, with proper provision for sweeping it, and then vertically above the roof. The fresh air flue is brought in the same way to the stove from an external wall. Such a stove is efficient, but is subject to the same criticism as the ventilating grate.

Gas Heating. This is receiving a great deal of scientific attention, and as a result has been greatly improved. The modern gas-stove is a very efficient form of heating apparatus, and has been largely used in recent years. In the stoves of best design, the knowledge gained from careful experiment has resulted in a gas-fire in which all the products of combustion are carried away by the flue. This is a most important point. These products are harmful. The claim made by some makers of flueless gas-stove, that they consume the products of combustion, must be accepted with the greatest caution. It can safely be asserted that there is no means known to science capable of application by which such a result can be accomplished. In the modern gas-stove the satisfactory features of the open fire are united, but the cost of the gas is very high—so high, in fact, that their use is generally restricted to small installations.

Electric Heating. This form of heating has been considered in detail on page 2733. It is easily installed, pleasant in appearance, and is free from products of combustion. The cost of current, however, is enormous, and entirely prevents its application on a large scale. It is a convenient means of heating small offices and rooms, on account of its high radiant heating power and its portability. One need not attempt to raise the temperature of any particular room in which it is used. It is generally possible to move the source of heat into a position in which the direct radiant heat can be felt, and a comfortable bodily temperature can be maintained in spite of a low air temperature.

Central Heating. There are several different systems of central heating. Within the last ten years a great advance has been made in this method of heating; most new buildings of any size have a heating plant. The system in most general use in this country is low-pressure

hot-water heating. Water possesses just such qualities which make it a splendid medium for distributing heat throughout a building. Its cheapness, high specific heat, and extreme fluidity are invaluable for this purpose. Its rapid increase in volume, and consequent fall in weight, when its temperature is raised, supplies the motive power which maintains the circulation.

The complete apparatus consists of three essential parts—the boiler where the temperature of the water is raised, the main pipes through which it is led to the points where heat is required, and the radiators where it gives out its heat to the surrounding air. Radiation, convection, and conduction, the three forms in which heat transmission can take place, each take their part in unison. It is for the heating engineer to see that no check is offered to any one of the three, for if one be checked all are checked.

Here the source of heat is the fire within the boiler. Its radiant heat falls on the plates which surround it; convection currents bear the highly heated gases from the fire through the boiler flues, which are heated by contact. The metal plates of the fire-box and flues conduct the heat to the water in contact with the other side; from here the convection currents of the water start out on their journey to the radiating surface. This is heated by contact, transmits the heat by conduction to the outer surface, where it is delivered to the air by contact, and also to some extent radiated into the rooms to be warmed.

How Circulation is Maintained. The circulation is maintained by the difference of temperature of the water in the flow and return mains. It is brought about by the expansion in volume which occurs when water is heated.

Before the fire is lighted in the boiler the water in the system is all of the same temperature. When the fire is lighted the water in the boiler expands and pushes its way into the flow main, which is connected to the top of the boiler. In doing so it causes water in the flow main to overflow into a tank provided for this purpose, which is fixed at the top of the flow main, and is called the expansion tank. Directly this happens, the water in the flow main is lighter than the water in the return main. The latter is connected from the top of the flow main to the bottom of the boiler. The water in it, now being heavier than the water in the flow main, begins to fall to the boiler, and the circulation is started. As it passes through the boiler, it in turn is heated, and so the circulation is maintained as long as the fire is burning.

From the flow main branch mains are led to the radiators. Here the heat is given out, and the water increases in weight again by contracting, and falls through the return branches to join the heavy stream of water passing through the return main on its way back to the boiler.

Design of Hot-water Apparatus. The design of a hot-water heating apparatus is complicated and difficult. The size of the boiler is obtained by adding the number of heat units that are necessary to warm each room, and also those which are given out by the main pipes. These units should be sufficient in number to warm the building to the required temperature in cold weather. The usual figures required are 60° F. inside, with an outside temperature of 32° F. Having arrived at the number of units required, the boiler capable of supplying that number per hour, making an allowance as a safety margin, is selected.

The size of the radiator is determined by the amount of heat that will be given out in cold weather by the different rooms. This depends not so much on the size of each room as on the amount of exposed wall surface, taking into account its thickness and the material of which it is made; also the size of the windows, the floor area when there is no heated room below, and ceiling area when there is no heated room above. The number of heat units given out for each degree difference in temperature between the radiator and the room temperature is known; so, having decided at what temperature the radiators are to work in cold weather, you can calculate their size.

Choice of Pipes. The most difficult part of the task is to calculate the correct pipe sizes for the mains and branches. The problem is to decide what sized pipe will be required to convey the necessary number of pounds of water per hour to each of the radiators, taking into account the resistance that will be offered to the flow of the water by friction with the pipe and in passing round the necessary bends and through the valves on its journey. If the pipe size selected is too small, the frictional resistance will be too high, with the result that insufficient hot water reaches the radiator to heat it properly. If, on the other hand, the pipe size is too large, too much water reaches the radiator, to the disadvantage of the other radiators in the system. It is very common to find that some of the radiators get hot, while others will not do so. This can generally be adjusted by using valves to regulate the flow through the various branches, but it is a long and costly process.

The real test of a well-designed apparatus is to see if all the radiators get hot with all the valves wide open; and if this test were applied a great number of heating systems would be found wanting. It is, however, quite possible to design an apparatus to fulfil this requirement, and it is a double advantage to the purchaser, because not only does the system work at a lower resistance, which means a saving in fuel, but the calculated cost is usually lower than that of a badly designed apparatus.

Fixing Pipes. In fixing the main pipes, care must be taken to arrange for a slight rise in them on the way out from the boiler, with a corresponding fall on the way back. To put this in the language of a hot-water engineer, you must avoid "dips" in the pipes. If a dip occurs, air, which is always given off where water is heated, will collect in the pipe just before the dip, and will cut off the circulation of the water. It is for the same reason that air-taps are always fixed at the top of radiators, and at the ends of branch mains, where they turn back to the boiler. These taps are occasionally opened, and a little air comes out before water. Sometimes air-pipes are carried up to a point above the level of the cold-water feed cistern, and through them the air passes out into the atmosphere whenever any is given off by the water. By this arrangement the system is kept continually "vented."

The Damper Regulator. Another very useful piece of apparatus which should always be used is called a *damper regulator*. It is fixed on the boiler, and a part of it projects into the heated water. If the water gets too hot, the regulator automatically closes the draught door below the fire-bars, and opens a check-draught door in the flue. This quickly has the effect of cooling the water

down, by retarding the rate of combustion in the fire. In the same way it increases the rate of combustion if the water begins to get cool. The better forms of this fitting maintain a wonderfully even temperature in the system. The apparatus can be adjusted to work at any desired temperature, thus ensuring a very even heating effect, and also securing a considerable economy in fuel.

Advantages of Hot-water Systems. The great advantage of the hot-water heating system is the economy in fuel. The modern types of heating boiler have an efficiency varying from 60 to 75 per cent., and it is no uncommon thing to find that it is possible to keep four rooms continually warm with the same amount of fuel as is required for warming one room with an ordinary open fire. It does away with cold draughts. If a house is warmed throughout, there is not the same necessity for keeping doors shut, and the air that slowly enters a room through the doorway, being warmed air, is not noticed. It adds considerably to the comfort of a dwelling if there are outlets in each room; such an outlet is usually found in the chimneys. Warmed air escapes up these, and so the necessary air change is secured.

Ventilating Radiators. Ventilating radiators are also made. They are constructed with a chamber for warming air, which is drawn in through the outside walls. The radiating surface, not being at a very high temperature, does not have such a bad effect on the incoming air as a ventilating grate or stove.

With this system it is easily possible to keep the house continually warmed, as the fire, even in small boilers, can be kept in all night.

The disadvantages are that it has a tendency to warm the air too much, and the radiators, not being at high temperature, are, in spite of their name, not good sources of radiant heat.

An Almost Ideal Combination. With a hot-water heating apparatus in combination with an open fire we get a nearly perfect heating and ventilating apparatus. The radiant heat is supplied by the fire, which also causes the air movement. The ventilating radiators supply the air at a comfortable temperature, and the air can be prevented from becoming too dry by humidifying pans, which can be fixed on the top of the radiators. Nothing can be more pleasant than a wood-log fire in a room heated with ventilating radiators, and no other arrangement approaches more closely to the physiological requirements.

There are other systems of central heating, which include high-pressure heating, steam heating, and hot-air heating, but none can compare with the hot-water system for warming houses.

Hot Water and its Storage. In these days a good supply of hot water is considered essential, even in houses of quite a humble character. This is usually arranged in connection with a boiler, heated by the kitchen fire, though in larger establishments an independent boiler is provided for heating water only. Flow and return mains are connected to the boiler in the same way as described in the hot-water system of warming. The circulation is also set up in the same way.

It is also essential in any such system to provide some means of storing hot water. The boiler, if heated by a kitchen fire, is necessarily of small capacity; and if the water in the boiler and the circulating mains was all that the system contained, it would be at a very high temperature, but would be very small in bulk. Such a system would very quickly be emptied when water was drawn off from any of the taps. In every system, therefore, a tank or cylinder, capable of holding a considerably larger bulk of water than the boiler, must be provided, but the size of this receptacle must be properly proportioned to the power of the boiler and the fire that heats it. The tank, when used, is usually fixed above the highest point at which it is required to draw off water, while a cylinder is fixed usually close to the boiler itself, and all draw-off taps are taken from the flow pipe above the cylinder.

The *tank system* [13] is the older form. Its chief drawback is that, in the event of the cold-water supply failing, the tank may be completely emptied by water being drawn off from taps, so that only the water in the boiler is left. This may be quickly converted into steam and evaporated, and the boiler left empty. Should this occur, the boiler is liable to become red hot, and to be damaged; and if the water supply is resumed while it is in this condition an explosion may occur owing to the sudden generation of steam.

The Boiler. The general arrangements of this system are as follow: the boiler is usually in the form of a *boot boiler* [8] or a *saddle boiler* [7], and is generally of iron, sometimes of copper. It is set at the back of the kitchen range. The flow pipe is taken from the top of the boiler, and it should be arranged so that its end does not project below the internal surface of the boiler. If it does so project, an air chamber is formed in the top of the boiler, which, though it may not interfere with circulation, results often in somewhat alarming noises in the boiler. The boiler must be provided with a small manhole to facilitate its examination and cleansing from time to time, and should have fixed to the flow pipe close to it a safety valve, properly weighted, which will allow of any steam generated in the boiler blowing off.

The Circulating Mains. The size of the flow pipe will depend upon the number and character of the taps that are to be supplied by it. It is taken from the boiler by the route that will most easily bring it near the various fittings it is intended to serve, to the tank, and must ascend gradually the whole of the way. The inclination need not be uniform throughout the length, but should never be less than 1 in. in 10 ft., and it is not desirable that pipes should be so nearly horizontal as this if it can be avoided. The reason for this regular rise is to allow the air, which is contained in all water, and which is driven off when it is heated, a free route of escape. If this is not provided, the air may collect in the pipe and impede or stop circulation. The flow pipe may be taken through the bottom of the tank, and is allowed to stand up in it for a considerable distance, or it may be connected through the side at a corresponding level. This is because the cooler water is at the bottom of the tank; and this arrangement ensures that, when a tap is opened, the water drawn from it will be taken from the upper and warmer layer of water and not from the bottom of the tank, with which the inflowing cold supply mingles.

The *return pipe* is taken from the bottom of this tank, and is returned by the easiest route to the boiler; and, like the flow pipe, this should never be quite horizontal, still less should it dip at any point. If it enters the boiler at the top, it must be continued inside the boiler, so as to deliver the water near the bottom, or it may be connected to the boiler by a side connection low down. The

circulation pipe should be of 1 in. diameter at least; and if the capacity of the tank exceeds forty gallons, or if more than four fittings are served, it should be 1¼ in., and for bigger installations even larger.

Branch Pipes. All branch pipes to apparatus, such as sinks, lavatories, baths, etc., are taken from the flow pipe, and it is desirable that all such branches should be as short as possible, for the water in them does not circulate, and therefore becomes cold. When the tap is first opened, all the cold water standing in the pipe must be drawn off before the hot water begins to flow, and it is desirable to reduce the amount of this to a minimum. The usual sizes for branch pipes are, for lavatories, ½ in.; for sinks, ¾ in.; for baths, ¾ in. or 1 in.

Cold-water Supply. This is an essential feature, and allows of water flowing in from the cold-water cistern to replace immediately any drawn off from the system when a tap is opened. The supply must be arranged so that, when water is drawn off, only hot water flows from the tap as long as there is any hot water in the system; but without skilful treatment it may easily happen that cold water will find its way to the tap and mingle with the hot and reduce its temperature. The hot-water tank must be fixed at a lower level than the cold cistern, with which it is in many cases directly connected by a pipe. There is no valve between the two systems, but a screw-down stop valve may be very usefully inserted, to shut off the supply in case of repairs. In order to prevent any chance of hot water working its way up the supply pipe into the cold cistern, this pipe should have a dip in it at least 6 in. deep just before it enters the tank [12]. It may enter the tank through the bottom and be finished with a T-piece to deliver the water horizontally and close to the bottom, or it may enter the cistern at the side close to the bottom, and may then be prolonged inside the cistern and finished with an elbow. The cold-water supply pipe should be 1 in. at least, except for quite small installations.

In some cases a feed cistern [13] is provided to supply the hot-water cistern only. This is connected directly with the tank, and is supplied by water from the main cistern through a ball valve. This effectually prevents any return of hot water to the main cistern, but there must be sufficient capacity in the feed cistern above the cold-water line to accommodate the increase of bulk due to heating the water.

Expansion Pipe. From the top of the tank a pipe is taken, of the same diameter as the flow pipe, and it is continued upwards to a point not less than 2 ft. above the cold-water cistern. In cases where the boiler is 60 ft. or more below the cistern, this height may be increased to 3 ft., and in either case the end of the pipe is bent downwards over the cistern. This pipe serves a double purpose—that of an expansion pipe to allow of the escape of water, and that of a vent pipe to allow of the escape of air. The expansion of water, when heated, has already been referred to, and in such a domestic apparatus may amount to from 2½ per cent. to 3 per cent. of the original bulk. If the system is charged with cold water and heat is applied, expansion will at once begin; and if no outlet is provided at some point it would force an outlet for itself. The water as it expands rises in the expansion pipe, and eventually overflows into the cold-water cistern, so that no waste of water occurs, and this continues till the water has reached its maximum bulk. Normally, the water stands in this pipe at the same level as in the cistern.

The Cylinder System. In this system [11] the vessel for storing hot water is placed near the boiler, and is therefore, owing to the head of water, subjected to a much greater pressure than the tank at the high level. The cylindrical form is therefore selected on account of its strength. The pressure exerted in any case may be calculated by allowing 1 lb. of pressure for every 2 ft. 4 in. of vertical height. The boiler is similar to that used in the tank system, and is connected to the cylinder with a flow and return pipe. The flow pipe should be connected with the cylinder at a point about two-thirds or three-quarters of its height from the bottom, and, if connected at a lower level, should have an internal pipe added to deliver the water heated by the boiler at this high level. The return to the boiler is taken from the bottom of the cylinder to the lower part of the boiler. The cold-water supply may be brought down and connected to the lower level of the cylinder in the same way as is described for the tank, or it may be connected to the return pipe. It should be of ample size, or the flow of water from the draw-off taps, especially those at a high level, may be checked. A full-way stop valve should be provided in this pipe near the cylinder, to facilitate repairs, but there is no other form of valve used. So far, this arrangement corresponds with that of the tank system, except that in this case the boiler and cylinder are very close together; but no draw-off tap is taken from the flow pipe between the boiler and the cylinder. A draw-off cock should, however, be fixed at the lowest point of the return pipe just before it enters the boiler, or in the boiler itself, to facilitate emptying the cylinder and boiler should examination or repairs be required. This should be fitted with a loose handle, which is kept separate from it, to ensure that it is used for no other purpose.

Secondary Circulation. In order to provide the necessary service to the various fittings, a secondary circulation is fitted up from the cylinder. The flow pipe is taken off the top of the cylinder, and is carried up as high as may be necessary to serve the highest fitting in the building to which hot water must be taken. From its highest point the return pipe descends to the cylinder, and is connected to it at a level above that at which the main flow pipe from the boiler delivers hot water into the cylinder. This arrangement secures that only the hottest water in the cylinder is circulated through this pipe. Though the terms *flow* and *return* are applied to this secondary circulation, draw-off taps may be taken from any point in the circuit, as there is no cold-water connection with any part of it. The expansion pipe is taken from the highest point in this secondary circulation to a level above the cold-water cistern, and arranged so as to deliver into it as described for the tank system. As the whole of the taps are connected to the secondary circulation which is above the cylinder, it is impossible that the latter can ever be accidentally emptied.

Conserving the Heat. The efficiency of the system may be considerably increased by surrounding the cylinder, and, when possible, the main pipes, with some non-conducting substance. For the cylinder, a thick layer of silicate cotton may be employed, kept in position by laggings of wood closely fitted and bound with iron or brass bands, which form a very neat finish. For the pipes, if

these are run in pipe casings, they may sometimes be packed in the same manner, or they may be wrapped round with asbestos sheeting. Either material prevents the cooling of the pipes to a very great extent, and tends to maintain the temperature of the water with but little loss.

Cylinder Tank System. This system is sometimes adopted, especially in large installations, and is essentially the same as the cylinder system, with the addition of a storage tank at a level above the highest draw-off. The advantage of this combination is that, with a large body of hot water above the highest tap, there is no danger of the water flowing sluggishly from any of the taps, as happens sometimes in upper floors in the cylinder system, while at the same time there is not the risk ordinarily attending the use of a tank, as the cylinder below renders it impossible to empty the system. But if a large body of water is to be heated and stored, a powerful boiler will be required, and with this system an independent boiler is often useful.

We have considered in some detail the methods of heating ordinary domestic buildings, including the hot-water supply, and must now consider the simpler means of ventilating such buildings, referring afterwards in more general terms to the more complicated systems in use in larger structures.

VENTILATION

The object of domestic and general ventilation is to secure an air change, and to keep the air in motion, the latter function being a valuable means of mixing up the air and preventing the accumulation of saturated air and air containing too much CO_2 in the part of the room where the occupants are. As previously stated, the investigations of Dr. Leonard Hill point conclusively to the fact that not so much fresh air need be supplied as was formerly thought to be necessary.

It will have been noticed that many of the ordinary appliances intended for heating are also valuable as ventilating agents. The open fire, ventilating grates, stoves, ventilating radiators, would all be included in a list of ventilating appliances in the system known as natural ventilation. There are several other appliances coming in the same class to which reference will now be made,

Ventilating Sash Windows. It is not always necessary to provide special openings for this purpose, as many modern sash windows are constructed to act as ventilating inlets, and answer admirably if suitably placed. This is done by making the bottom rail of the bottom sash of extra depth, and providing a deep bead above the sill in the inside [**14**]. The lower sash of such a window may be raised two or three inches without being lifted above this bead, so that air is not admitted at the sill level; but the top rail of the lower sash will be raised, and an opening formed at this point between the lower and upper sash, at which air can freely enter, which will be delivered in the room at a considerable height, generally above the level of the heads of the occupants. Such an arrangement will have less tendency to produce a perceptible draught than having the window closed and letting air force its way in between the sashes and the frame, for it is important to remember that the larger the opening, the lower will be the velocity with which any given volume of air will pass through it in a given time. When, however, there is a considerable difference between the internal and external temperature, if cold air is admitted it is almost impossible, even with this arrangement, to avoid the sensation of draught.

Special Ventilating Openings. If windows are not made use of, special inlets may be made in the external walls, and provided with fixed gratings externally, and with some form of movable grating or valve internally. Such an opening should not pass straight through the wall from its outer to its inner face, but should be bent upwards in the thickness of the wall.

The external gratings may be of iron or terra-cotta, and are intended to prevent birds nesting in the openings. The internal surface of the flue itself should be smooth, without sharp angles, and may be formed in Portland cement and sand, trowelled, or may be lined with a metal tube. The internal grating may be what is termed a *hit-and-miss grating* [**15**], which consists of two metal plates perforated in identical manner, which allows the passage of air through both sets of openings when they correspond in position; but when one of them is shifted sideways the solid parts of one grating lie over the openings of the other, and either wholly or partially check the passage of air. Many forms of valved gratings are employed. In some a kind of hopper head is allowed to fall forward when air is to be admitted, and is raised again when it is to be closed [**16**]. In others a diaphragm is fixed on a pivot, which can be turned so as to open or close the passage as desired.

Tobin Tubes. Another form of inlet is the apparatus known as a Tobin tube [**18**]. This consists of a short vertical tube, generally about 6 to 7 ft. high, which may readily be inserted in an existing building. It is usually formed of wood, and, if so, must be well framed and glued up, so that the joints are perfectly air-tight. It may have a metal lining, which is generally of zinc. The horizontal sectional area will vary according to the cubical capacity of the room to be ventilated; but the sectional area of the tube, or, if there are several in one room, their united area, should be calculated so as to give, at the very least, 25 sq. in. for every 1000 cubic ft. of air space. The lower end is connected with the external air, and protected by a grating. Such tubes may sometimes be usefully placed against an internal wall when an air-trunk can be taken under the floor or in its thickness to such a position. The upper end is usually open, but covered with a fine grating, and the air is delivered with an upward tendency. Such a tube may be fitted with a diaphragm in its course, so that the opening may be either closed or wholly or partially opened.

It will be noticed that the apparatus described under the last three headings all allow air to pass into a room from the outside. Although they are very useful when the external air is above 55° F., they cannot be used if the temperature falls much lower, and they are consequently constructed so that they can be closed.

Positions of Ventilating Openings. There is much difference of opinion as to the best positions for inlets and outlets, but the general tendency is to place the inlets high up on the wall and the outlets low down, so that expired air and the products of combustion from lamps and gas-burners, as they are produced, are withdrawn from the lower parts of the room. It is often advocated that the two openings should be at different levels in the same side of the room, and that this arrangement tends to promote the most complete circulation of air, while others advocate placing inlets

and outlets in opposite walls. Much will depend on whether there is only one inlet or outlet in a room, or if there be more than one. In the latter case, it should be possible to avoid any stagnation of air in any part of the room when the inlets and outlets are placed in opposite walls.

An outlet is not infrequently formed into the smoke flue of a fireplace, near the ceiling level, which must be provided with a mica valve, similar to that used in a fresh-air inlet. This will allow air to pass through it from the room into the flue, but will prevent air and smoke passing into the room from the flue.

Ventilating gas-burners have been much employed for certain classes of buildings, and less frequently for private houses. In these the heat generated by the combustion of the gas is taken advantage of to create a current of air in a specially arranged outlet tube, which will carry off the vitiated and heated air that collects in the upper part of a room when no other means of ventilation are provided.

Ventilating Domestic Offices. Before leaving the subject of natural ventilation, it is advisable to point out that it is necessary to ventilate not only rooms used by human beings, but rooms used for preparing and storing human food, and rooms which contain sanitary conveniences. In the case of the latter, it is very undesirable that air should be drawn from them into other parts of the building, though this is usually difficult to prevent. Such chambers are rarely heated, and tend to form a source from which cold air may readily be drawn, as in many cases some permanent opening direct to the external air is insisted upon. When such chambers are heated, they should be kept at a higher temperature than that of adjoining passages and rooms, the result of which will be that any movement of air that takes place will be into the chamber rather than out of it.

Prevention of Stagnation. Ventilation must also be provided in all positions in which air would tend to become stagnant, especially if there is at the same time, any tendency to moisture and heat. In the case of a store-room or cupboard having no external window, it often suffices to bore two sets of holes, about 2 in. in diameter, one set near the top of the door and the other a few inches above the floor level.

The space under the lowest floor of a building, if the floor is not laid solidly on concrete, is a position in which the importance of ventilation is paramount. If none is provided, the air becomes stagnant, and the timbers are liable to decay from the attack of fungous growths and from dry rot. It is therefore essential that openings be provided in external walls [17], and in any cross-walls such as will allow of a free circulation of air under all parts of such a floor. Further, as already pointed out [on page 2725], it is important that all hollow spaces formed when walls are built in two thicknesses, and when dry areas are provided, should be efficiently ventilated.

Mechanical Ventilation. The other system of ventilation, in which some mechanical means is adopted to secure the necessary air change, is usually employed in large buildings and institutions. In it there are two systems of ducts—those which deliver the air to various rooms, and those which carry the used-up air away. The motive force employed to move the air is generally a fan driven by an electric motor. The mechanical power is employed usually in one of two ways. It either forces the air into the building, when it is known as the *Plenum system*, or it extracts the air from the building, when it is known as the *Extractum system*. In many instances the two systems are combined, in which case fans are used to draw air in, and also to draw it out.

In both systems the fresh air is brought in through a main duct, where it can be heated, filtered, and moistened, and then distributed through branch ducts into the various rooms to be ventilated.

In the "Plenum" system it is not necessary to treat the ducts through which the air leaves the building in the same way. Each room may have its own outlet directly into the open, care being taken that any wind pressure which will occur on the side of the building cannot force its way in through the outlets, or prevent air from coming out. To get over this difficulty it is the usual practice to form vertical ducts in the internal walls, carried right up above the roof level, and protected from down-draught.

In the "Extractum" system, in which the air is drawn out, a similar arrangement for the outlet ducts must be provided as for the inlet ducts; they must all unite with one main extraction duct, in which the extract fan is fixed.

In smaller systems, the extraction is sometimes secured by means of heat. Large gas-rings, heating coils, and even furnaces are sometimes used. The extract ducts are led to the point where heat is applied, and a vertical flue is carried up above the roof level, closed at the top, but provided with louvre openings on all four sides into the outside air. The application of heat at this point, where it cannot assist in warming the building, is recognised as wasteful, and the method has been largely superseded by the use of electric fans, which can be operated at a very low cost.

Before leaving the subject, reference should be made to the use of an independent electric fan working within a room and not in a duct connected to the outside air. Dr. Hill's experiment has clearly shown the utility of such a fan; and it can be strongly recommended as a means of maintaining a movement of the air within a room. The only precaution necessary is to see that it does not blow directly on to the occupants.

LIGHTING

The adequate lighting of all parts of a building is a matter of the utmost importance to its comfortable use. The lighting by day is secured by the provision of openings of sufficient size and suitably placed to admit daylight to all parts; and the success of this treatment will somewhat depend on the adequacy of the areas from which light is derived. In towns these are to some extent regulated by Building Acts or by-laws, which regulate the height of buildings in streets of various widths, and the extent of open space that must be provided in the rear of such buildings. These regulations are mainly directed to the provision of spaces not wholly inadequate, into which the windows for lighting various rooms may open, and from which both light and air may be obtained. In many cases regulations are also made as to the size of internal courts provided as areas for light. In the case of London, in buildings erected in newly laid-out streets, the provisions are intended to secure that if a line is drawn from the ground level of a building on one side of a street to the eaves or parapet of the opposite building, the angle it makes with the horizon shall not exceed 45°. In the case of a window obtaining light from a court, the line drawn from the sill to the eaves or parapet of the opposite wall must not make a greater angle than 62½°; and in the case of the open area at the back, while the

angle varies somewhat according to the actual height, the conditions secured are rather better than those in an internal court. These are general rules, modified in the case of buildings irregular in plan, and in the case of buildings laid out in old streets or replacing older buildings destroyed or taken down. All such provisions must be carefully observed, and represent the minimum requirements for towns, and, wherever possible, more favourable conditions should be provided. In particular, an effort should be made to secure that in a domestic building every habitable room should receive at some time in the day not merely daylight, but sunshine, which is of the utmost importance from the point of view of health.

Darkness, as well as stagnation of air, favours the development of many noxious germs, and it is important, therefore, that not only the habitable rooms but the corridors, staircases, and the various offices of such buildings should be adequately lighted in every part. In many buildings the conditions governing the place may make it difficult or even impossible to provide for the complete lighting of every part, but it is a consummation to be aimed at, and approached as nearly as may be.

Artificial Lighting. It is absolutely essential, in addition to securing an adequate provision of daylight, to provide some means of artificial illumination, by means of which the various occupations of life may be continued after daylight has failed. At no time has the means of doing so been so complete and efficient as at the present day. Immense strides have been made within the last thirty years, due to the introduction of electricity as an illuminant suitable for domestic lighting. Not only is the light itself admirable from many points of view, but it has stimulated the inventive powers of those interested in gas-lighting, and led indirectly to great improvements in this branch of lighting also.

It is not necessary to do more than refer to the older forms of illuminant—candles and oil lamps—as they do not involve any special preparation in the course of the construction of a building, and, in its finishing, only require the provision in some cases of suitable brackets or holders for the lights. But it may be pointed out that lamps certainly have shared in the general improvement, and that both candles and lamps are in many respects pleasant forms of illumination, and must, even in these days, be relied upon by a very large class of householder—by those who live in districts not served by any public gas or electric company, and whose requirements are not sufficient to warrant the establishment of a generating plant for either illuminant.

The drawbacks to their use are mainly expense and the trouble of daily attention, and the risk of damage to carpets and furniture, often due to carrying about such movable lights. Such means of illumination are, however, sometimes used to supplement both gas and electric light installations, which are not always carried into every part of a building.

In the case of buildings situated so that there is no public supply of gas or electricity available, it is possible, if the circumstances warrant the outlay, to establish a private generating station for either gas or electricity, but it is not possible to deal in this article with the details of such installations. It is, however, comparatively rare to find private installations for generating coal-gas. Such an apparatus requires skilled attention, and it would be possible to supply gas economically only in the case of a large mansion.

Acetylene Gas. *Acetylene gas* is another form of illuminant that in recent years has come largely into use for such moderate installations; it gives an exceedingly good light, and is, as a rule, less expensive than a gas installation. For an equal amount of illumination the cost is usually estimated as equivalent to that of gas supplied at from 3s. to 3s. 6d. per 1000 cubic ft. The principal drawback to its use is the extremely unpleasant odour that is apparent if the combustion is not absolutely complete.

The great advantage of such an installation is that it does not require any constant or highly skilled attention, but may be operated by a gardener, and will not, at the outside, take more than a few minutes' attention daily. The gas and its installation are dealt with, in detail, on pages 5540 and 5541.

From the holder the supply pipe to the house is taken. A governor to regulate the pressure, which is otherwise variable, is usefully added, and the pipe first descends to a low level, from which it may rise regularly to the house. At the lowest level a small tube or container is fixed to catch any water flowing back from the service pipe, with a tap by which it may be emptied. The supply pipe is usually iron; copper must not be used for supply pipes or in fittings which will come in contact with the gas, as an explosive compound is liable to be formed.

Service Pipes. The service pipes are arranged as for ordinary gas supply, as already described [page 5369], but the consumption of gas is very much less, and somewhat smaller pipes may be employed. Great care is required in making all joints so as to prevent any escape of the gas, which has a sickly, unpleasant smell, and is, as already stated, highly inflammable. It is usually best to employ steam-piping rather than ordinary gas-piping, and to see that the screwed joints are sound and made with the smallest possible amount of white lead, as joints that would be perfectly tight when ordinary coal-gas is employed will permit the escape of acetylene.

Acetylene Gas Fittings. The fittings used with acetylene gas may be high-class gasfittings or special fittings, the important point being to ensure absolute soundness in the joints and cocks, to prevent the smallest escape of gas. The burners are of special form [see page 5541]. The holes for delivering gas are very minute, and are arranged so that the gas jets from two holes impinge and produce a flat flame. The burners are arranged on the Bunsen system, so that atmospheric air is mixed with the gas before combustion; and the most recent form of burner, introduced by Messrs. Bray & Co., overcomes a difficulty that when a gas flame was turned down the burner was apt to become carbonised, so that it was difficult to use a burner except at full power.

The most usual size of burners are the following:

Burner consuming $\frac{1}{3}$ cubic ft. per hour, giving a light of 6·2 candles.

Burner consuming $\frac{1}{2}$ cubic ft. per hour, giving a light of 17·5 candles.

Burner consuming $\frac{5}{8}$ cubic ft. per hour, giving a light of 35 candles.

Hydrogen Gas Fittings. The fittings used for ordinary coal or hydrogen gas were briefly referred to in the article on gasfitting [page 5369]. It is, perhaps, hardly necessary to point out that so far as the form of the fitting and its artistic treatment is concerned there is room for almost infinite variety, and such matters are regulated by individual taste, the money available, and the character

of the building in which they are to be placed. But whether the fitting be a bracket or a pendant, fixed or movable, of iron, brass, or copper, plain or elaborate, its main purpose is to provide at a suitable point in some room or hall a burner which will supply gas at a point where illumination is required. The number and disposition of lights, whatever the illuminant, require careful consideration, and depend greatly on the use to be made of the particular chamber. The following table gives the appropriate amount of lighting that is usually considered requisite for various classes of building, but this is subject to variation in individual cases, and, in particular, if the height of the fitting is varied from the normal position.

	Per 1000 sq. ft. area,
County district roads	¼ candle power
Towns (urban)	4 ,,
Cities and boroughs	10 ,,
Dwelling-houses (principal room)	250 ,,
Cottages (principal room)	150 ,,
Hospitals	50 to 100 ,,
Schools	300 ,,
Churches and chapels	300 ,,

This is a matter of considerable importance, for it must be remembered that the illuminating power of any illuminant as affecting any object varies, not according to the distance that separates them, but according to the square of the distance; and if, therefore, lights are fixed at an unusually high level, they must be much more powerful to produce the same effect at the floor level.

Gas-burners. The ordinary gas-burner is arranged so as to produce a flat flame. The orifice is formed in a very refractory substance, *steatite*, mounted in a brass holder provided with a screw, by which it can be attached to any form of bracket or pendant. The commonest form is known as a *bat's-wing* burner, and is formed with a thin slit in a cone-like termination from which the gas issues. The *slit union* is somewhat similar, but the termination is spherical. The *union jet* has two small circular perforations, from which the jets impinge and form a flat, slightly cup-shaped flame. None of these ordinary forms of burners secure the complete combustion of the gas or the highest amount of illumination from that which is consumed, and they require fairly frequent renewal in order to get satisfactory results, but they are in all cases inexpensive, and easily fixed and renewed by the householder himself, without calling in the gasfitter. Such burners are usually protected by glass or china globes; and if placed within 3 ft. of a ceiling or of any woodwork there should be a talc top fixed over the globe, or a glass or metal bell fixed over the light. In public institutions the flame is often protected by a wire globe secured to the fitting, and this is a very useful precaution in the case of a swing bracket which might be swung into contact with any inflammable material.

Improved Burners. An improvement on the simple burner is one fitted with an *economiser*, which is really a second burner of greater capacity, placed over the inner one, producing a larger flame without a greater supply of gas, and securing more complete combustion. Other burners are fitted with some arrangement of governor, by which the pressure at the burner is regulated, though the pressure in the service pipe is subject to fluctuation. There are several varieties of such burner on the market. The *Argand burner* is one arranged to produce a circular flame similar to that produced from the circular wick of an oil-lamp. The burner is circular in form, with an air space in the centre, and a series of small apertures are formed from which the gas issues, so that a ring of flame is produced. Air has access to the middle part of the flame, which is enclosed with a wide glass chimney.

Incandescent Burners. The most striking innovation in the use of gas in recent years has been the introduction of what are known as *incandescent* burners, which have, to a great extent, revolutionised gas-lighting. The best known form of burner for the domestic purpose is the Welsbach C. burner. This consists of a burner producing a hot flame which impinges on a mantle suspended directly over it, and which is heated and maintained by the flame in an incandescent condition, producing a brilliant illuminating surface. The mantles are impregnated with *thorium*, and are somewhat delicate, and their life is uncertain. When used in this way the gas may be mixed with atmospheric air, as in an ordinary Bunsen burner, and used to the greatest advantage, with the approximate result that with a reduction of 50 per cent. in gas consumption the illuminating power is doubled. The burner is also somewhat expensive in the first case, and the maintenance of mantles is a considerable item, but for equal illumination there is, in spite of this outlay, a very great economy in the use of incandescent lighting, as compared with other forms, accompanied by a more complete gas consumption.

An inverted incandescent burner may now be obtained, in which all the metal parts of the fitting are above the mantle, which therefore throws no shadow on a table over which it is placed, and in this respect attains one of the great advantages secured by most electric lamps.

Electric Lighting. Electric lighting is dealt with in detail on pages 2339 and 2467. Its advantages are:

The light, being turned on and off by the movement of a switch, conduces greatly to the economical use of the light; the absence of heat and all products of combustion, which in the case of all forms of gas-lighting contribute to the vitiation of the atmosphere of rooms, the gradual destruction of decorations, and the blackening of ceilings; the safety from fire where the installation is well executed, which is also effected by the absence of all unprotected lights, and the absence of all use of matches.

To set against this is the increased cost of electricty over gas for an equal amount of lighting, but this is a matter that depends very much upon the way in which the installation is planned out and used. Very great economies may result from the careful arrangements of fittings and proper provisions for turning on and off the lights in a group separately or in small groups. It should also be borne in mind that while the cost per candle-power is higher in the case of electrlcity, as compared with gas, it does not follow that the cost per fitting is correspondingly as high, at any rate when comparison is made with an ordinary gas-burner, as a very much more brilliant light is often obtained, for which a higher price may properly be expected. When the great saving in the cost of redecorating work is taken into account, and a little care is taken not to burn light wastefully, it is found in many cases that the cost of lighting a house throughout by electricity is not very greatly above that of lighting it by gas. Electricity is more readily produced than coal-gas in small quantities, and is eminently suited for private installations of moderate size, but the attention of a skilled mechanic is necessary, so that it is not adapted for work of a very small character.

Strand, Concentric, and Three-Core Cables. Conductors and Insulation. Making, Covering, and Testing. Joining. Systems of Laying.

CABLE MAKING AND LAYING

For the distribution of electricity in large quantities, cables are in general use. The electrical cable is an insulated or separated artificial path or track along which electricity will flow readily. The path is a metal core, known as the *conductor*, and the material which separates it from the surrounding objects is known as the *insulation*. Copper has been found to conduct better than most other substances, hence we find the conductor in nearly all cables made of a copper-wire rope or strand. The insulation is a coating of a material which will not allow electricity to pass through, or along it, except under very great pressure; therefore, when this material is placed round the core, the current flowing through the conductor is entirely separated from objects around it and is consequently under control.

Insulation. Insulations fall naturally into two classes: (1) *hygroscopic*, or moisture absorbing; and (2) *non-hygroscopic*, or moisture resisting. The more common of the first class are jute and paper, and of the second, vulcanised indiarubber, gutta-percha, and bitumen.

The first successful experiment in which a continuously insulated cable was used was in 1812, when Baron Schilling exploded a mine by electricity conveyed by a wire insulated with indiarubber, and laid across the River Neva. In 1815, or 1816, Ronalds carried out some experiments in telegraphy, and, in addition to an overhead wire, which was suspended by silk threads hanging from wooden frames, he had one, a little less than a furlong in length, underground. This was drawn through glass tubes, the separate lengths of which were joined together by small glass sleeves placed over the joints and fastened in position with wax. The glass tubes containing the wire were then placed in a wooden trough and covered over with pitch. This method of insulation was not very successful, as the glass was very liable to break and leave the wire uninsulated. The stranding of wires was introduced when large sectional area and flexibility were required. In 1837, a line was laid in London in which the wires were covered with cotton steeped in resinous compound, and then laid in grooves cut in baulks of wood. The insulation of these wires soon gave way, because the cotton decomposed and left the wires practically bare. The dampness which caused the decomposition also acted as a conductor, and allowed the electricity to escape.

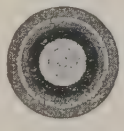
In the following year a line was laid from Paddington to Slough. In this instance the wood was replaced by iron pipes; but the line had the same fate as its predecessor, and an overhead system was substituted. In 1845, a proposal made by Wheatstone and Cook to enclose the cotton-covered wires in lead tubes, was a step in the right direction, and a patent was taken out in the same year for lead-covered wires. Cables covered with lead gave much better results than previous ones, and about this time a new insulation was discovered in gutta-percha, Faraday being one of the men who found that it was a good insulator. The first wires insulated with gutta-percha were laid in London in cast-iron pipes in the year 1849.

Conductors. The chief conductor nowadays is the copper-wire strand or rope. The separate strands which form this rope are usually tinned in order to keep their surfaces clean, because tarnished copper is not so good a conductor as clean copper. The most commonly used moisture-resisting insulators now in use are indiarubber, bitumen, and gutta-percha, and the principal moisture-absorbing, jute and paper. The india-rubber insulation is laid on in two kinds. The first kind, which touches the copper strand, is pure and free from sulphur, because sulphur tarnishes metals. The second kind is a compounded rubber containing sulphur. This will vulcanise and become firm and resilient. The bitumen is first thoroughly refined and then mixed with sulphur and other chemicals, and vulcanised like the second layer of rubber. Before the bitumen is applied, a layer of thin rubber-coated cotton tape or paper is wound round the strand to prevent the sulphur in the bitumen tarnishing the copper. Gutta-percha is used in a flexible state chiefly for low-pressure work, such as telegraphic insulations.

The paper used for insulating purposes is strong manilla paper soaked in resinous compound. The jute is usually applied in the form of a braid impregnated with oily compound.

So far, mention has been made only of the two essentials in a cable—namely, the conductor and the insulation; but it is not often that one meets with a cable in use made only of these two. Nearly every cable has some extra coverings, either to make the insulation perfectly waterproof, or to give the cable some mechanical protection. Lead sheathing, steel tapes, galvanised iron wires, and jute braid are extensively used for these purposes, as will be shown in the following descriptions of cable-making.

Varieties of Cables. Of the several kinds of electric lighting and power cables made, the most widely used are the "Single," the "Concentric," the "Twin," the "Triple concentric," and the "Three-core." The *single* cable [1] consists of a central copper strand, a layer of insulating material, a covering of braid, and a sheathing of protective armouring.



1. STRAND CABLE

The process of making a "single" indiarubber insulated cable begins with the conductor. The copper wire for this purpose has usually a tin coating, and comes from the makers, when not drawn at the cable works, in hanks. These hanks are sorted into the various sizes of wire, and the desired size for the cable about to be made is chosen, and thoroughly cleaned to remove all traces of tarnish, dirt, and grease. After being cleaned and examined, single lengths of the copper wire are wound on separate small metal drums or bobbins, which fit round the circular frame of the stranding machine. The number of drums used at one time, and the size of wire wound upon them, depend upon the amount of current the finished cable will have to conduct. A large number, of a large size, are required for a large current. When the drums are in position there is passed through the centre of the machine a central wire to which the ends of all the

wires on the small drums are attached. As this central wire is drawn along the machine is set in motion and the frame containing the drums rotates in such a manner that it twists or strands all the other wires round the central one, so as to convert them into a wire rope or strand [see page 2248].

Applying the Insulator. If the conductor is free from grit and grease after this operation, it is ready to receive its covering of insulation. For this purpose, if it is a small-sized cable, it is taken to the longitudinal machine, which consists of a long, raised bed, at each end of which there is a pair of grooved rollers. Rolls of narrow indiarubber strip are placed before each pair of rollers, the first lot being pure, and the second one compound indiarubber. As the end of the conductor is brought up to the first pair of rollers, the ends of two strips of pure rubber are placed about it, one on top and one below; so that when it comes out at the back of the grooves the indiarubber strips are pressed round in the form of a complete covering, with a firmly-pressed longitudinal joint at each side. Although this joint is made only by pressure, yet if the surfaces of the edges of the strips are perfectly clean, it is thoroughly sound. On approaching the second rollers, two strips of compound rubber are applied in a similar manner, so that when the conductor finally passes out of the machine, it is completely covered with two layers of indiarubber.

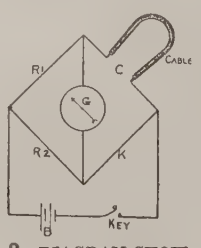
If the cable is of large size, the two kinds of indiarubber are applied by the lapping machine, which covers the conductor by spirally wrapping the indiarubber strips round it instead of pressing them on as at the longitudinal machine. The wrapping of large cables is preferred because the pressure given by the longitudinal machine has not been found satisfactory for the greater thickness of insulation required by them. The separate layers of strips are wrapped in reverse spiral so as to prevent, as far as may be, the possibility of a weak spot in each of two strips, occurring right through the insulation at one place. The thickness of the rubber coating is decided by the considerations of the pressure and disruptive strain that the insulation will have to withstand.

The Indiarubber Covering. When the requisite thickness of indiarubber has been applied, the cable is given a wrapping of indiarubber-covered cotton tape, at the taping machine. This is to add firmness to the covering of indiarubber, which, up to this time, is a plastic substance, of the consistency of stiff dough. In this state it can be easily moulded into any desired shape, and will stick in the shape it is formed. This, of course, is very convenient while the indiarubber is being pressed or wrapped on the conductor, but before the armouring materials are applied over the insulation, it is necessary that it should be firmer and more resilient. With the object of giving these properties to the substance it is taken to the vulcanising house. This is a room containing large, hollow, cylindrical, iron pans to which the necessary pipes, taps, valves, etc., are attached, so that steam may be let in or out as desired. In this room the cable is placed inside one of the pans, after being wound on the drum made especially for the purpose. The pan is closed up by a steam-tight door, and the steam turned on until a certain pressure is reached. This pressure is kept up for a certain time, until the indiarubber is properly vulcanised. The pressure and time of vulcanisation depend upon the quality and thickness of the rubber applied. When the steam in the pan has been let off, and the cable taken out and cooled, it will be found that the outer layer of indiarubber has acquired the desired properties of firmness and resiliency. The acquisition of these properties is chiefly due to the indiarubber containing as one of its ingredients sulphur, which is a vulcanising agent, and which, under the action of steam pressure, chemically combines with the other ingredients and gives the springiness so characteristic of all indiarubber goods. The full chemical action which takes place is not thoroughly understood even in indiarubber manufactures. During the whole process of applying and vulcanising the rubber great care is taken that the surface is quite clean and free from grease of any kind, as the successful manufacture of vulcanised indiarubber cables greatly depends upon the careful handling of the indiarubber.

The cable is now completed as far as its essentials are concerned—it has its conductor and its finished insulation; therefore, before any further coverings are added, either for protection against dampness or mechanical injury, it is taken to the test-house to be tested. Here the cable undergoes a rough test under water, to see that its insulation is sound. A second and more careful test is given when the cable is complete, details of which process will be given later.

Braiding the Cable. If, after the rough test, the insulation is found satisfactory, the cable is allowed to dry, and is then taken to the braiding machine to be covered with a stout jute braid. This braid is moisture-absorbing, and in order to prevent it from rotting, it must be protected from damp. For this purpose the cable covered with braid is passed through the serving tanks, which contain a hot compound, composed chiefly of paraffin wax, and similar substances. The coating of compound on the braid as it comes out of the tanks, besides being damp resisting, is also an insulator, and therefore adds a little to the better insulation of the finished cable. Since indiarubber is a waterproof material, it is not necessary to cover the cable with a lead sheathing, although one is sometimes put on for mechanical protection. The more common method of protecting indiarubber insulated cables against mechanical injury is by encasing them with galvanised iron wires or steel tapes. The wires are stranded over the jute braid by the stranding machine, and the steel tapes are wrapped on by the steel taping machine. Although the iron wires are galvanised as a protection against rust, yet a jute braiding is often applied on the outside of them as a further safeguard.

Testing the Cable. The cable is now ready for its final test, and for this purpose it is taken to the test-house, placed in tanks of water, and allowed to remain there for about twenty-four hours. The testing operation is very important, and takes a day or two to complete. The chief tests made by the makers are those of the conductor, the insulation resistance, and the capacity of the cable.



2. DIAGRAM SHOWING CABLE TESTING

The test of the conductor is usually made by comparing its resistance with that of a known resistance. The comparison may be rapidly made by an instrument known as the Wheatstone bridge [see also page 759]. A simplified diagram of the connections for the comparison is shown in **2.**

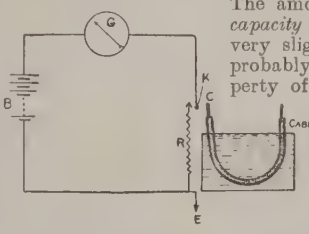
The proportion of the resistance through R1 and R2 is the same as that through C and K when the current passing round the arms causes no deflection in the galvanometer G. R1 and R2 may be read off the bridge scale, and K is a known resistance; therefore the resistance of the conductor under test is easily found from the formula

$$\frac{R1}{R2} = \frac{C}{K} \text{ or } R1 \times K = R2 \times C.$$

Suppose the proportion of R1 and R2 is 2 1, and the known resistance equals 5 units; then from the second formula the cable will have a resistance of 2×5, or 10 units. Another method of testing the conductor is by the metre bridge, the principle of which is somewhat similar.

The Water Test. The test for the insulation is made after the cable has been in water, at a constant temperature, for twenty-four hours. With the cable still in water, the insulation resistance is tested by a method of comparison. The leakage current through the insulation is compared, by means of a galvanometer, with the flow of current through a known high resistance, when the same battery power is applied. The galvanometer is an instrument in which there is a sensitive needle, placed over a graduated circular scale, and surrounded by a coil of wire. This is its simplest form [see page 368].

As the current passes through the galvanometer, the needle is deflected through a certain angle. The comparison, in its simplest form, is made thus: Suppose a circuit is made up of a battery, a galvanometer, and a length of wire. After the current has passed round the circuit for a short time the galvanometer needle will remain stationary at a certain deflection from its original position. If the wire is now taken out, and another one of equal length, but of different substance, put in its place, the galvanometer needle, when the current is next sent round the circuit, will come to rest at a deflection different from the one in the first instance. In both these circuits the battery, the galvanometer, and the length of the wire are the same; the only difference is the substance of the wires, therefore any change in the current can be due only to this alteration. Now the current in a circuit is approximately equal to the electromotive force sent out by the battery, divided by the resistance offered to this force by the wires or other substances in the circuit. If the electromotive force is represented by E, the resistance by R, and the current by C, then $C = \frac{E}{R}$. Applying this formula to both instances above, we see that E is the same in both, but C, as shown by the deflection of the needle, is different; therefore the resistance must have altered in inverse proportion to the current. A numerical example will make this clear. Suppose the battery sends out a force of 6 units and gives a deflection, in the first instance, of, say, 30°, and in the second of 20°. Then since the current is proportional to the deflection, we may take it that the first current equals 3 units, and the second 2; and from the formula $C = \frac{E}{R}$ we get, first, $3 = \frac{6}{R}$, and second, $2 = \frac{6}{R}$. Therefore the first resistance equals 2 units, and the second 3 units. Thus the second wire has a resistance of one and a half times the first one.



3. CONNECTIONS FOR INSULATION TESTING

Insulation Resistance Test. In the actual testing of cables the resistance which the insulation should offer when sound is first calculated, and the circuit is made up of a powerful battery, a galvanometer, and a known high resistance, which is approximately equal to what the calculation gives. Figure 3 shows a diagram of connections for insulation resistance testing. A deflection is obtained with the known resistance in circuit by pressing the key K into contact with R. The known resistance is disconnected, and one pole of the battery is connected through the galvanometer to one end of the cable by pressing the key to the right to make contact with C. The other end of the cable is left entirely free, not even allowed to touch the sides of the tank in which the body of the cable lies. The other pole of the battery is connected to earth at E. To complete the circuit, the electricity will have to flow from the battery through the galvanometer into the cable, through the insulation into the water, down the sides of the tank to earth, and along the earth to the wire earthed at E. Thus it will be noticed that the electricity will have to go *through* the insulation as it had to go *through* the known high resistance, and since these are, approximately, equal, the deflection obtained when the cable is in circuit should be nearly the same as that when the known resistance was in. This will be the case when the cable's insulation is sound, and when the ends, which are never allowed to touch the water, are painted with paraffin wax for the purpose of preventing surface leakage.

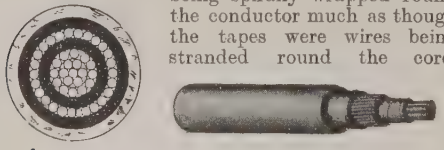
A point may be mentioned with regard to reading the galvanometer deflection when the cable is in circuit. When the electricity enters the instrument, a deflection will be shown, but as the electricity continues to flow the deflection will gradually decrease for a few minutes, and then remain stationary. This slow decrease is due to the electrification of the cable; that is, the absorption by the cable of a certain quantity of electricity into itself. The amount of absorption is known as the *capacity* of the cable. If the decrease is very slight, or proceeds unsteadily, there is probably a defect in the cable. This property of electrification may be used as a further test for the soundness of the cable in this way. If after electrification the cable is connected to earth through the galvanometer after the battery has been removed, the deflection of the galvanometer will show that a steadily decreasing current is flowing from the cable. If the deflection decreases at the same rate as when the battery was first put on, the cable is sound.

Testing Capacity. The capacity of the cable may be tested by comparing it with a condenser of known capacity. The condenser is first charged by a battery, and then the accumulated charge is sent through a galvanometer. The cable is first connected to earth to remove all residual charge, and then electricity is sent through it until it has absorbed to its full capacity. This point is reached when the galvanometer needle remains steady. The battery is removed, and the cable connected to earth through the galvanometer, and the deflection compared with that obtained from the condenser. The capacities are roughly in proportion to the deflections.

Concentric Cables. These consist [4] of a prime central conductor, an insulation covering, a second conductor outside the insulation, a second insulation on top of the second conductor, and a protective covering. The second conductor is in the form of a copper wire ring, which is concentric with the prime conductor. The insulation in this make of cable is usually of paper or jute. The reason for this is that the second conductor could not be well applied on a soft indiarubber insulation before vulcanisation, because it might cut through the plastic substance and cause a fault. Further, if the first insulation were vulcanised before the second conductor were added, the second insulation would have to be vulcanised, and while this was being done the first insulation would be vulcanised again. This would destroy all the good properties of the first covering, and cause it to crack when bent.

To appreciate the necessity for this precaution, it should be recognised that the vulcanisation of rubber is not a definite chemical reaction between the added sulphur and the rubber. The sulphur is invariably added in some excess, and the condition of the finished article determined not only by the amount of sulphur added, but by the degree of heat applied and the length of time the vulcanisation occupies. The degrees of vulcanisation are, for practical purposes, infinite. Starting at one end of the scale, we have rubber vulcanised on the surface only by the application of a liquid containing sulphur; then by gentle gradients the scale can be ascended until vulcanite itself is reached, which is no longer an elastic body, but a hard material containing up to 50 per cent. of sulphur, and which has been exposed to a higher temperature and for a longer length of time.

Making Concentric Cables. In the making of concentric cables, the first process is the making of the central stranded conductor by means of the stranding machine, as already mentioned. The conductor is taken from the stranding machine to the paper-lapping machine, where it receives a covering of several layers of strong manilla paper tape. This is applied by being spirally wrapped round the conductor much as though the tapes were wires being stranded round the core.



4. CONCENTRIC CABLE—LEAD COVERED

Each layer of paper is wrapped on in reverse spiral, for the reason stated, with rubber strips. The paper-covered core is now placed in a hot-air chamber, heated to about 250°, to drive out all moisture. Since the paper will again absorb moisture from the atmosphere if left about, it is at once taken to the tanks containing a special hot resinous compound. The paper is thoroughly impregnated with this compound until it is practically waterproof. At the same time, the compound adds a little to the better insulation of the cable. From the tanks the cable is again taken to the stranding machine, where it receives its second conductor. This requires careful application, since, when it is on, the wires forming it must have a combined sectional area equal to that of the prime conductor, because both will have to carry the same amount of current with the same amount of resistance. If the sectional area differed, the smaller conductor would offer more resistance than the greater to the passage of the same amount of electricity. This would cause waste of current and more heat in the circuit, therefore both conductors should be of the same sectional area. The second insulation is now applied by the wrapping, drying, and impregnating processes as before.

Lead Covering. With a moisture-absorbing material like paper a waterproof covering is necessary; therefore, as the cable comes out of the compound tanks for the second time it is taken to the hydraulic lead press to be encased with a lead sheathing. The method of applying this has been much discussed among cable-makers, some preferring to put on the lead at a high temperature with low pressure, and others at a lower temperature with high pressure.

In the former method, the lead is very liable to small air holes, or pores, and the thickness of the sheathing is not usually the same all the way round. In the second method, owing to the increased pressure, porosity is less likely to occur, and the thickness of the covering is more smoothly and evenly maintained; hence the high pressure process is now becoming general. At the hydraulic press the cable passes through the centre of a die, through which the lead is forced at the same time under very great pressure and at a temperature well below melting point. This gives the cable a closely-fitting protective sheathing against dampness and mechanical injury. With the lead covering on, the cable is ready for testing. In connection with these paper-insulated cables, the great difficulty is to prevent dampness getting to the insulation, because dampness not only conducts electricity, but also quickly rots the paper and causes a fault. When a fault occurs, there is no telling what may happen, so that it behoves makers to see that the cable is sound before it leaves the works.

Testing Lead-covered Cables. The testing of lead-covered cables is rather difficult to conduct in a satisfactory manner. The cable is first placed in water-tanks, and left there for about twenty-four hours, the ends being carefully kept out of the water, because they are not fully protected against dampness. When the test for insulation resistance is made, the ends are carefully prepared to prevent surface leakage by being coated over with an insulating compound. Both the waterproof and the insulation resistance tests are very similar to those for india-rubber insulated cables. It will be noticed that the concentric cable is not tested as soon as the insulation is applied, as the single cable was, and the reason for this will be readily understood when it is remembered that the chief idea right through the process of making the cable is to prevent dampness in the paper.

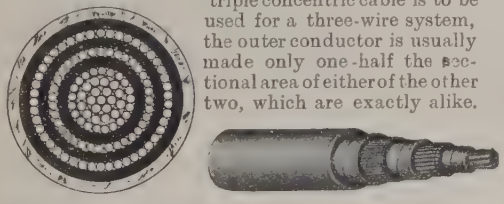
The unsatisfactory part of the testing when the lead covering is on is this: owing to the method of application, there is always the possibility of weak places occurring in the lead. These will withstand the tests when the cable is newly made and before it has been wound many times on a drum, but very soon after it comes to be wound and unwound in the process of laying, the weak places break down, and when next the electricity is sent through there is a fault shown. After the testing the cable is ready for use. Since lead soon decomposes when laid in the ground, this class of cable is usually laid in conduits. The concentric cable, having two conductors, may be used alone.

Twin Cable. This is called a twin cable [5] because it has two similar insulated conductors bound together under one protective covering. The two conductors are stranded separately at the machine, and each is separately insulated by indiarubber, bitumen, or paper.

5. TWIN CABLE—DOUBLE-STEEL TAPE ARMOURED

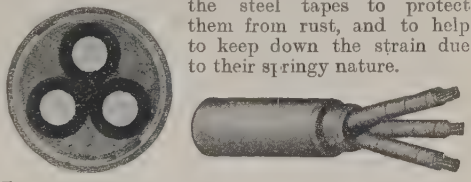
As the conductors are usually small in twin cables, they can generally receive their insulation, if of indiarubber, at the longitudinal machine. If bitumen or paper is used, the insulation is applied by the wrapping process. After receiving the insulation of indiarubber, the cables are tested in a manner similar to the single indiarubber cable. Up to the testing process the two conductors are treated as separate cables, but from this point they become as one. If they withstand the tests satisfactorily, they are placed side by side and closely packed round with broken jute, usually impregnated with resinous or tarry compounds. A stout jute braid is then applied round the packing to keep it tightly in its place, and to make a solid core around which a lead covering or wire armouring may be placed. Before the armouring is applied, the braided cable is passed through the serving tanks to receive its covering of compound, which acts as a preventive against dampness. The lead covering is also put on for this purpose, but it further acts as a mechanical protection.

Triple Concentric Cable. This [6] is so called on account of the three concentric conductors which are enclosed within its armouring. It consists of a central conductor, a first layer of insulation, a second conductor in the form of a ring, a second layer of insulation outside the ring, then a third conductor, again in the form of a ring of copper wire, and a third insulation. As the insulation is usually of paper, for the reasons stated for the concentric cable, the usual protective covering is the waterproof lead sheath applied by pressure. The stranding of the conductors, the wrapping of the insulation, and the pressing on of the lead are all done in the manner as described for the concentric cable. If the triple concentric cable is to be used for a three-wire system, the outer conductor is usually made only one-half the sectional area of either of the other two, which are exactly alike.



6. TRIPLE CONCENTRIC CABLE—LEAD COVERED

Three-core Cables. This cable [7], as the name implies, has three cores or conductors, each of which is separately stranded and insulated. All three are then bound together within one armouring. A sample of the three core cable before the writer is insulated with bitumen. To prepare this substance for insulation purposes, it must go through a thorough refining process. Much difficulty was at one time experienced in getting this material into such a condition that it was neither so brittle as to crack when bent nor so soft as to allow the heavy conductor to become decentralised when insulated with it. After the refining process the bitumen is compounded with chemicals, one of which is sulphur, and rolled into thin sheets. These are cut into narrow strips, which are wrapped spirally round the conductor, after a lapping of paper or indiarubber-covered cotton tape has been applied on the copper to prevent the sulphur in the bitumen from tarnishing it. The process of vulcanisation is the same as for indiarubber, and it is done for the purpose of adding strength and flexibility to the compound. Each conductor is generally of the same size, and insulated with the same thickness of material. When the insulation is vulcanised, the three cores are placed together and tightly packed round with jute soaked in oily or bituminous compound. A strong braid surrounds the packing, and on the outside of this the armouring is placed. This may take the form of galvanised iron wires, steel tapes, or lead sheathing. If steel tapes are used, they are applied by the steel taping machine and laid on in two spiral layers. The second layer is wound over the joints of the first, so that there is no joint showing right through the steel covering. Steel tapes are an excellent form of mechanical protection, as they are flexible and will withstand a lot of rough treatment without injuring anything underneath them. A covering of strong braid is usually placed over the steel tapes to protect them from rust, and to help to keep down the strain due to their springy nature.



7. SEVEN-STRAND THREE-CORE ARMOURED CABLE

Joining Cables. In the above descriptions only single lengths of cable have been dealt with. When a long cable is required, several of these lengths have to be joined together. The joining operation is very difficult, and much care must be taken in order to make a sound job. In the making of a joint the considerations to be borne in mind are that the joint should offer a resistance as near as possible to that of any other part of the conductor, the insulation about the joint should be as sound as any other portion of the cable, and the joint should be strong enough to withstand a certain amount of rough usage which it is sure to receive when being laid. The method of making the joint varies somewhat with the style of cable being joined. A common way of fastening together two lengths of small size cable (say, nineteen strand) is by what is known as the *married joint* [8]. To make this the conductors are stripped of their insulation for a short distance from the ends about to be joined. The bare conductors are then bound round with a few turns of thin copper binding wire at the place where the insulation ends. This is to keep the strands in place while the outer wires are bent back so as to disclose the central strands of seven wires. These are soldered up solid for some distance and then filed into a long bevel so that when placed together there will be a fairly large surface of each in contact with the other. The two ends are then held together while they are tightly bound with binding wire. The joint is then

soldered over and filed down smooth. The wires should be thoroughly cleaned before joining so that the solder will run well on them. The outer wires, which have been bent back, are now cut off at suitable lengths, alternate ones of each conductor being cut long and short. These are then butted together so that a long wire from one side butts against a short one of the other, and molten solder is poured over the joints, after binding wire has been wrapped over them. Figure 8 shows this joint.

The solder is filed down to smoothness so that there will be no sharp projections which might pierce the insulation. The reason for cutting off the outer wires in alternate long and short lengths is to avoid the overlapping of the wires and to make the finished joint as nearly as possible the same thickness as any other portion of the conductor. If the conductor is a very small one (say, of only seven wires), it is usually joined by one joint in a similar manner to the central strand as described above.

The Telescopic Joint. Another simple way of joining small cables is by the telescope joint as shown in 9. To make this the conductors are stripped of their insulation for a short distance and then bound with wire as before. The outer wires of one conductor are then cut off at the binding, and the inner strand of the other is cut off at its binding. The outside wires, B, now remaining are laid up in position again so that they form a hollow cylinder into which the projecting central strand, A, of the first conductor, after being soldered up solid, is inserted. The end of the hollow cylinder touches the binding at which the outer wires were cut off. The whole joint is tightly bound with wire, and then soldered over and filed down smooth, after which it is ready for insulating.

In the concentric cable the inner conductor is joined by the single or married joint, according to size, and then insulated, the outer wires, or the second conductor, having been turned back out of the way. A sleeve of clean copper is usually placed over the joint on the outside of the first insulation, and on the top of this sleeve the second conductor is married, bound, and soldered as mentioned before. In joining concentric cables great care must be used so that the first insulation shall not be damaged in any way during the process of joining the second conductor. The second insulation is applied and then the protective covering.

Joint Boxes. Large cables are usually joined in specially made joint boxes filled up solid with compound to make them watertight and to improve the insulation.

When joint boxes are not used the insulation of the joints in cables is a very difficult matter, as will be readily understood when it is stated that these are the places in which the conductor will offer most resistance and consequently generate most heat. Further, the insulation will have to be tightly and soundly applied without any of its properties being impaired in any way. There are two ways of reinsulating the joints in indiarubber-covered cables; one by means of pure indiarubber, and the other by vulcanising indiarubber. The pure indiarubber joint is made by stripping back the tapes and braids so that they will be clear of the part to be reinsulated. When the indiarubber is thick enough the surface which has been exposed during the making of the copper joint should be trimmed down to the conductor in a long bevel.

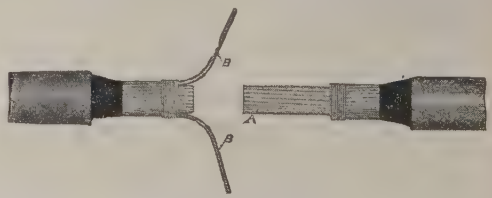
This will expose a new, clean surface, to which the pure indiarubber strip about to be applied will stick better. If the copper joint is clean and smooth, the pure indiarubber strip is wrapped tightly and evenly round it, and over the bevelled surfaces, until a thickness equal to, or slightly greater than, that of the old covering is obtained. Strong tapes are then soaked in compound and tightly wrapped over the strip, and for a short distance over the original braiding. The whole joint is then

8. MARRIED JOINT

painted over with resinous, water-resisting compound. When the indiarubber insulation is not thick enough to be bevelled down, the new rubber may be lapped for about an inch or so over the old, which ought first to be well scraped and cleaned to remove all grease and dirt. This kind of reinsulation of joints answers all practical purposes in indoor low-pressure circuits where little moisture penetrates and little heat is generated.

Joining Cables Out of Doors. The making of a vulcanised indiarubber joint out of doors requires special apparatus, since it is practically impossible to carry about with one a steam generating plant and vulcanising pans. The molten sulphur bath is probably the most satisfactory portable vulcaniser for outside work. The bath may consist of a strong, cylindrical box, made in halves, and flanged so that they may be bolted together to enclose the joint. The upper half contains a hole through which the molten sulphur is poured, and through which a thermometer is placed so that the temperature of the sulphur can be read. The bottom half contains a tap, through which the sulphur is run out after the process is over. When the box is screwed up with the joint inside, the openings through which the cable passes are packed with common rubber to protect the insulation from the heated flanges.

The preparation of the joint for the insulation is similar to that described above. When the bevelled edges have been cleaned, a lapping of pure indiarubber strip is tightly applied so that it just overlaps the thin edge of the bevel. On the top of this the strips of vulcanising indiarubber are firmly



9. TELESCOPE JOINT

wrapped until the insulation about the joint is the same diameter as any other portion of the cable. The tightness and evenness of wrapping are essential to prevent small air spaces being left between the layers of insulation. A spiral wrapping of indiarubber-covered tape is placed over the vulcanising

THE CABLE THAT LIES ON THE OCEAN BED

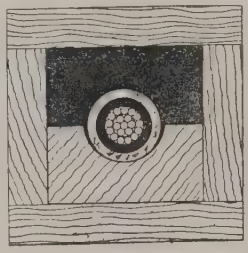
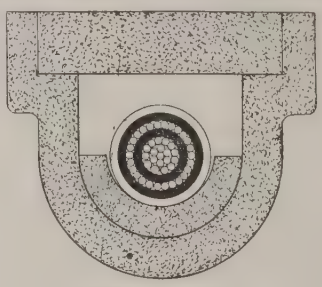
rubber, and in order to keep the insulation in shape, and under pressure, a piece of sheeting is tightly rolled over the tape so as to form a longitudinal seam. On this a spiral wrapping of strong unprepared tape is applied. The sheeting and unprepared tape merely act as a mould while the joint is being vulcanised. As soon as the process is over both are removed. The sulphur is melted over the fire used for heating the soldering irons, and is poured through the top hole in the box. The temperature is maintained by placing spirit lamps under the box. It is advisable to heat the box first so that the temperature of the sulphur will not be greatly diminished when it comes into contact with the metal. After the sulphur has been kept at the proper temperature for the requisite time, it is run out, the box is unbolted, and the joint allowed to cool. The operation is over. A rough test for the degree of vulcanisation may be made by pressing the indiarubber, when cool, with the thumbnail. If this leaves no mark, the rubber may be considered to be correctly cured. If a mark is left the indiarubber is probably under-vulcanised, and if the substance feels hard and solid so that the nail makes no impression, over-vulcanisation has probably occurred. The vulcanised joint is protected by strong tapes and braid, which overlap for a short distance the original braid on the cable. Joints in bitumen-insulated cables are made in a similar manner to those described above, but the paper cables are more commonly joined in special joint boxes, which are watertight and take the place of lead covering.



10. SOLID SYSTEM OF CABLE LAYING

Testing Joints. When the joints are completed, they should be tested to see that their insulation resistance is not much different from that of an equal length of continuous cable. There are several ways of testing joints, but a simple and effective one is known as the accumulation method. The joint to be tested is placed in water contained in a trough which is thoroughly insulated by being raised from the ground on blocks of insulating material.

The trough should be tested before proceeding with any other tests. The length of cable containing the joint is connected to one pole of a battery, the other pole of which is connected, through a condenser, to the water by a wire, which is not allowed to touch the cable. The current passing through the insulation of the joint escapes through the water and along the wire to the condenser. This is then disconnected from the trough and connected to a galvanometer, through which the condensed or accumulated current passes, and gives a deflection. The joined length of cable is removed and a continuous piece substituted; the condenser is again connected with the trough and again collects the current passing through the resistance of the cable under test. The battery is kept on for the same time in both cases. The second accumulated current is sent through the galvanometer as before, and if the deflection obtained in the second case varies but slightly from that of the first, the joint may be considered satisfactory.



11. CONCENTRIC CABLE LAID IN STONEWARE CONDUIT

The trough may be tested by passing a current through an electrometer until a steady deflection is obtained. The battery is removed and the electrometer connected to the trough. A decrease in the deflection of the instrument takes place, but if this decrease is only very slight, the trough is sufficiently well insulated for testing purposes.

Cable Laying. When the joints are tested and found sound the finished cable is ready for laying. The question of whether the cable should be laid underground or overhead is soon decided. In England the only method allowed in any of the large towns is the underground system, although under certain circumstances, especially for the transmission of electricity over long distances, the overhead lines may have decided advantages. Overhead wires are chiefly confined to outlying mining districts. There are many in South Wales. The several ways of laying cables underground may be grouped into two classes: (1) the "built-in," or "solid" system and (2) the "drawn-in" system. Figure **10** shows a lead-covered cable laid on the solid system, and **11** shows a cable laid in a conduit in the "drawn-in" system.

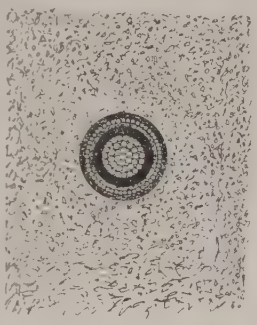
Access to built-in cables, when once they are laid, can be made only by opening up the ground, whereas in the drawn-in system, the cables, lying as they do in conduits, may be easily withdrawn into the nearest surface box for inspection. Greater mechanical protection is required in the "solid" method than in the "drawn-in." This is because the cables in the solid system are sometimes laid in the ground direct [12]. The armouring may consist of steel tapes, or iron wires, or the cables may be laid in troughs of wood or iron, filled up solid with compound. Sometimes broad tiles are placed just above the cables to give warning to workmen when opening the ground that the cable is at hand. Precautions are then taken that the pick or spade is not sent through the cable's insulation. In these troughs a good plan is to lay the cables on small bridges of wood, as shown in **10**, before filling up with the compound or asphalt.

Whichever of these plans is adopted, the cables must be laid while the ground is open, and this is a great inconvenience to traffic if the laying happens to be in a very busy thoroughfare. Further, the road authorities allow only a certain length of trench to be open at one time, and this is often a hindrance to rapid laying. When a length of trench is prepared, the drum containing the cable is mounted on a trolley and wheeled along the side of the trench so that it pays off the cable, which is laid in place in the trough. Hot compound is then poured over it. The trench is filled up, and the surface repaved.

Drawn-in System of Laying. In the "drawn-in" system it is not necessary to go to the expense of strongly armouring the cables because they are provided with mechanical protection by the conduits into which they are drawn. The pipes or conduits are placed in the ground before the cables are drawn into them, and when once they are in position the ground need not again be opened. For the purpose of drawing the hauling line through the conduits, a wire is threaded through each section

of them, as they are laid, and it is fastened in the surface boxes. When the conduits are laid, the drum containing the cable is conveniently placed on an axle near the mouth of a surface box, and the end of the cable is connected, by a smooth, strong, fastening, to the hauling line, which is then drawn through the conduits by the wire left for that purpose. The rope is then used for drawing in the cable. The length of cable which may be drawn in at one hauling depends partly upon the weight of the cable but chiefly upon the straightness of the conduits about to be entered. In town work the lengths are usually short on account of the numerous sharp bends encountered. When a bend is reached, a length of cable, sufficient to reach to the next surface box, is drawn through and laid on the ground in long loops. The hauling rope is drawn on as before, and then the loops of cable gradually disappear into the conduits. The reason for raising the length of cable to the surface at the bend is to avoid the friction and extreme tension which would arise from the cable being drawn round a sharp corner. Even in straight lengths of conduit the friction is very great, and to reduce this as far as possible a coating of whiting is often applied, as a lubricant, to the cable. Sometimes a chain is drawn through the pipes to clear away any obstacles which might increase the friction or tension on the cable that follows. If the conduits are smooth to begin with, and these precautions are taken against friction, the possibility of damage to the cable during the drawing-in is reduced to a minimum.

Conduits. The cost of conduits is a considerable item. When large-sized cables are laid, a separate way is usually provided for each one, although smaller sizes may be drawn in in pairs. This question of cost has led many people to turn their attention to the manufacture of cheaper kinds of pipes which can be readily joined together. Brick culverts are rarely used now because they take up much space underground, they occupy a long time in building, and are very costly. Earthenware conduits, with two or three cable-ways, can be laid much more quickly and cheaply, and they are now manufactured in a special way so that the joints can be easily made. The disadvantage of earthenware pipes is that they are very liable to fracture, and on account of this other kinds are sometimes substituted.



12. WIRE-ARMOURED CABLE LAID DIRECT IN THE GROUND

Bituminous concrete conduits are often used because they are fairly cheap. They are made in blocks with two or more passages, and are joined together by inserting short mandrels in each passage of two blocks while hot bituminous compound is poured into the joint and allowed to cool. When the mandrels are withdrawn the compound has formed a joint between the two blocks, and the mandrils have kept clear the passages through which the cables will be drawn. Cast-iron pipes are extensively used in connection with Post Office cables, as they have been found to be the most satisfactory.

Considerations in Laying. In deciding at any place whether the cables shall be laid by the "solid" or "drawn-in" systems, considerations are given chiefly to the cost of the cables and conduits. If the "built-in" cables are laid in iron troughs filled up solid with compound and the "drawn-in" system has cast-iron pipes for conduits, then the cheaper method is probably the latter, as in this the cables are not usually so strongly armoured as in the former. After the cost the convenience of access in the "drawn-in" system strongly recommends this method, although it has several disadvantages. The conduits are always liable to infiltrations of water and gases, and if the insulation is not perfectly waterproof, a fault may easily occur. Further, wherever gas collects there is always the possibility of an explosion. The conduits are usually connected with the drain pipes so that the water may run out almost as quickly as it enters. In the solid system there are no spaces in which gas may collect, and the insulation is usually waterproof, therefore the small amount of water which may penetrate the compound around it may be ignored.

Uses of Different Insulations. The different kinds of insulations mentioned have their respective advantages and disadvantages for special classes of work. For a material to be a good insulator it should be moisture-resisting, because moisture is a conductor, and lowers the effectiveness of the insulation; it must be strong and tough, so that it can withstand the rough usage it receives in laying without splitting or tearing, and it should be flexible so that it can be easily wound on drums or bent round sharp corners underground. Further, it is desirable that it should withstand a fairly high temperature without being injured permanently, as heat is generated by the passage of the current along the conductor, and it should be practically unaffected by the acids and gases it is likely to meet when laid in the earth. In high-pressure circuits the insulation must be a very homogeneous mass, because it has to offer great resistance to disruptive discharge. When an installation is found with all or most of these properties, the best cable is that in which the cost, bulk, and weight are least. Good quality of indiarubber, properly applied, possesses almost all these qualities; therefore, from a purely technical point of view it is undoubtedly the best insulator known. Its one great disadvantage is that it is expensive.

Bitumen compound is a fairly good insulator for low-pressure work, but as it cannot withstand much heat without softening, it is unsuitable for heavy current work, where a large amount of heat is generated. Its resistance, thickness for thickness, is not quite so good as indiarubber, but it has the advantage of being cheap. Gutta-percha has a comparatively low melting point, and is therefore confined chiefly to insulation of submarine cables, and underground telephone and telegraph wires, which work only at low pressure. The advantages of gutta-percha for these insulations are that it is thoroughly waterproof and lasting. Paper insulations are suitable for either high or low pressure circuits as they will withstand a fair amount of heat without serious injury. Their disadvantages are that the paper readily absorbs moisture and therefore always requires a lead or other variety of waterproof covering, which adds to the expense. The paper itself is inexpensive.

Voice Production and the Vocal Organs. Classification and Characteristics of Different Voices. Breathing Exercises.

HOW TO SING

It would not be true to say that a voice can be created or made by a teacher of singing; but all voices, good, bad and indifferent, may certainly be greatly improved and developed by a proper method of voice production.

The First Essentials. It is not enough to sing the melody perfectly and pronounce the words clearly; more than these qualifications are needed. A perfect understanding of the subtleties of a song is required if the listener is to be moved. The student should try to realise, as he sings, how he would feel were the words of the song his own and the outcome of his own feelings.

It is possible for everybody to do this, although in some natures the gift is more developed than in others.

The artistic side of the art of singing, however, should never tempt any singer to neglect or depreciate the technical side of it. It is essential that the æsthetic part of singing should be preceded by a thorough technical study.

First and chief of such studies is a correct method of breathing. Too great importance cannot be attached to this. Some of the old Italian singing masters used to say that "breathing well meant singing well." Perhaps this is rather an exaggerative assertion, but, at any rate, it is certain that a person cannot sing properly if he cannot breathe properly. It requires diligent and careful practice, but if the student will be advised by a thorough and experienced teacher, he will surely make up his mind at the very beginning thoroughly to master the art of respiration.

Training the Vocal Organs. Having at last so far succeeded in this all-important study, he may then turn his attention to the training of the vocal organs. It must be borne in mind that voice production cannot be forced; it must be developed slowly and surely, or the result will be disastrous.

The study of songs must not be entered upon at too early a date; let the student work at scales, exercises and solfeggi until he is able to sing them without being in the least conscious that he possesses a throat, or, in other words, until his production is perfectly easy. He will then be able to give the whole of his attention to the meaning of the words and the conception of the song, because, through careful, conscientious, and regular practice the technical side of his art will have become "second nature" to him.

It is not the singing voice alone that is benefited; the speaking voice, too, receives a large share of the profits.

Four distinct attributes are essential to musical sound—*Volume, Pitch, Quality,* and *Duration.*

Volume (strong or weak) depends upon the vocal cords, the resonance chambers, and the relative amount of breath pressure.

Pitch (the height or depth of a note) depends upon the number of vibrations in a given time.

Quality depends upon the pharynx principally, together with the cavities of the chest, mouth and head, which act as resonators.

Duration depends entirely upon the breath.

The production of very few voices, either in singing or in speaking, is quite perfect. The voice should be trained in order to make it respond to the will, to make it firm, reliable, strong, and flexible, easy to use, and to ensure correct intonation (to help a person to sing in tune); to point out and correct faults; to understand the art of phrasing; to bring out the various degrees of expression, and to become familiar with the different styles of singing.

How the Voice is Produced. The human voice cannot be described as any particular instrument or thing. To produce it there must be four distinct organs, working together, but quite independent of each other. They are:

The Bellows, properly termed the lungs, together with the wind or breath.

The Voice-box, properly called the larynx.

The Resonator, properly called the pharynx, together with the mouth and nasal cavities.

The Articulator, which consists of the tongue, teeth, lips and mouth.

Given these four requisites, voice can be produced by filling the lungs with air and allowing it to pass out through the mouth. A man, mentally, though probably unconsciously, says he wishes to utter a sound, or to sing; the breath is the motive power, and as it passes from the lungs it travels through numerous tubes until it reaches the larynx or Adam's Apple. In the Adam's Apple, or voice-box, are two ligaments which lie across the throat from front to back. When the order is given for a sound to be produced, these ligaments unconsciously close, and the breath strikes against the edges of them, setting them vibrating or oscillating, and the issue is voice, or sound. The ligaments are generally called the vocal cords or vocal lips.

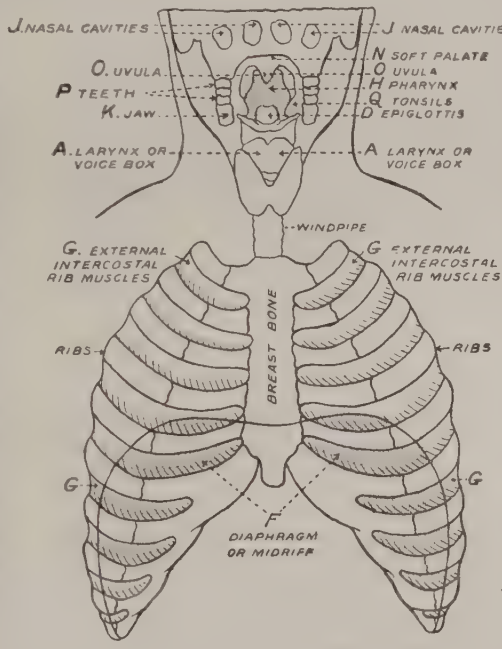
It requires careful study and much thought fully to understand the parts used in tone-formation.

Naturally it is much more difficult to grasp the principles of singing than of instrumental playing, because the student can *see* the different movements and actions necessary, whereas with the singer much has to be taken for granted.

He has to trust chiefly to his hearing—which at best is only an after-effect—for he cannot, except mentally, direct his vocal cords, and certainly cannot see them working. There must, of course, be no trusting to chance. It is very important that he must know exactly what tone and effect he is striving for, and, to acquire these desired effects, it is necessary to know something of the anatomy of the vocal instrument. In order that the student shall not become wearied, the descriptions of the various organs used in voice production are set down as concisely as possible [1 and 2].

The Larynx. The apparatus by which vocal sounds are produced is called the larynx, which is the special organ of phonation. It is placed at the top of the windpipe, immediately under the floor of the mouth. If the fingers are lightly placed on the projecting part in the forepart of the neck, it will be found that, when swallowing, that part moves up and down, and that is the larynx or voice-box, more commonly called Adam's Apple. It is triangular in shape, and open at both ends, top and bottom, so that the breath can pass in and out from the lungs. It is more noticeable in men than in women, and it is easy to see it move up and down as they talk. [1A]

Vocal Cords. Inside the triangular-shaped box, or larynx, are two flat horizontal folds, or cords, which stretch across the throat from the front to the back. These are the vocal cords. It is the greater or less tension of these, together with the breath, that gives us what we know as sound or voice. The higher the pitch of the note, the greater is the tension and more closely together are the vocal cords. [2B]



1. THE PRODUCTION OF THE VOICE

The Glottis. The space between the vocal cords is called the chink of the glottis. [2C]

The Epiglottis. At the top of the larynx is a self-acting cover, or lid, which is not unlike a bird's tongue to look at. Directly a person wishes to swallow, this little lid, called the epiglottis, shuts down tightly, like a miniature trapdoor, on to the windpipe (trachea), the object being to prevent food from passing into the larynx. Who has not felt the unpleasant sensation of choking when food has gone the "wrong way"? This happens when the epiglottis does not do its work quickly enough. [1D]

The Lungs. The lungs, which are two in number, called the right and left, are the bellows of the human body. They are a very spongy and elastic tissue, and may be likened to two sponges. They are capable of great expansion and contraction, and are placed, or, to be more correct, suspended in the upper part of the body, which is called the chest (thorax). They are connected to the windpipe by two tubes, which divide and subdivide until the size of the smallest pipe, if such it can be called, is about the fortieth part of an inch long. At the end of each tube, or pipe, is a minute air-cell. In the chest, which is an air-tight compartment, the lungs and the heart fit quite closely. The floor of the chest is known as the diaphragm, of which more will be said later. The walls or sides are formed by the ribs, together with the breast-bone. [2E]

The ceiling, or top, is formed by the ribs, collar-bone, and the root of the neck. The lungs rest, as it were, on the diaphragm. The size of the lungs depends entirely upon the size and build of the body. Their colour is a kind of purple, or rather dark bluish red. Their chief work is to supply the blood with pure air and to free it from carbonic acid; it is quite necessary therefore always to breathe fresh air.

The Diaphragm or Midriff. The largest muscle in the body is an involuntary one, called the diaphragm, or midriff. It divides the upper part (the chest) from the lower (the stomach); that is, it lies across the body. The outer parts are fixed to the lower ribs.

When the lungs are almost empty, or, in other words, during the act of exhalation, the diaphragm is almost dome-like in shape. As the lungs fill with air they press on the diaphragm until it becomes much flatter in appearance. Only will power can control this huge muscle, and, as it plays such a very important part in the art of respiration, the student cannot be too diligent in his endeavour mentally to control it. [1F].

The Rib Muscles. On each side of the chest there are twelve ribs, making twenty-four in all. Each is connected with the backbone or vertebral column; they curve round to the front, and seven pairs, counting downwards from the neck, are joined to the breast-bone;

the eighth, ninth and tenth are joined to the seventh, whilst the eleventh and twelfth pairs are not attached to any part in the front, and are commonly called the "floating" ribs. Connected with the ribs are two kinds of muscles—the outer and the inner *intercostals*. As the lungs become inflated the outer intercostals raise the ribs upwards and outwards. As the lungs empty themselves, the inner intercostals come into play and bring the ribs back to their former position. The student's attention is drawn particularly to the movements of these muscles, as a thorough understanding of their working is essential before he can master the art of breathing. [1G]

The Pharynx. The pharynx, or throat chamber, is the cavity situated in the upper part of the throat, behind the mouth. There are five openings into it—from the ear, nose, lungs, mouth and stomach.

The throat chamber is subject to great variations, being capable of great expansion and contraction. It is the principal resonance chamber of the voice. The colour and timbre, as a matter of fact, depend almost entirely upon it. [1H]

The Nasal Cavities. The nasal cavities are really the external and internal nostrils; the last named join the pharynx. The hard and soft palates make a floor for them. The nasal cavities assist very considerably in tone production, by helping to make the voice more resonant. [2J]

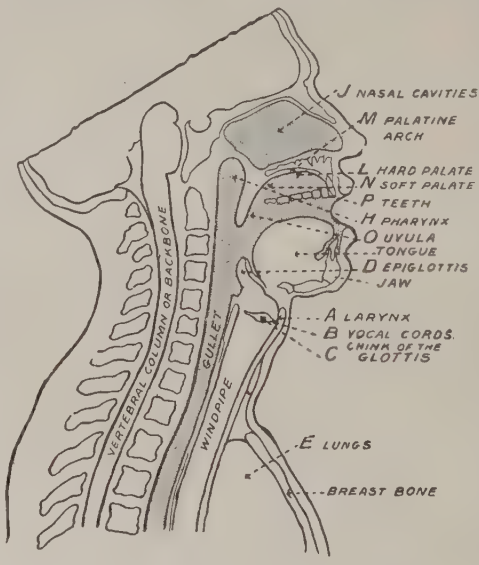
The Jaw. The lower jaw plays a very prominent part in the art of singing, helping principally in pronunciation. It is essential that it should be kept loose and free. Lamperti, in his famous "Treatise on Singing," attaches great importance to this. When the jaw is loose and free, so are the muscles of the throat. The distance between the teeth should never be less than a thumb's width when singing. [2K]

Hard Palate. If the student places his finger inside his mouth immediately behind the upper teeth, he will find a hard, fixed and slightly ribbed substance; it is known as the hard palate. On moving his finger a little further along the hard palate, he will come to a dome-like part; this is called the Palatine Arch [2M]; these two greatly influence vocal tone. [2L]

Soft Palate. Carrying the finger still further into the mouth, the student will come to a very sensitive, soft, fleshy and movable part of the roof, which possibly he may not be able to touch without feeling sick. This is called the soft palate. It consists of a number of muscles which work at will. If the student draws in a breath through the mouth as if he were going to yawn, he will feel his soft palate rise, and it will appear to become a continuation of the hard palate. He should practise raising his soft palate in this way, so that when he sings he will be able to raise or lower his palate at will. One of the most common faults of singers of the present day is their inability to do this, and in consequence they almost invariably sing with their palates "down." This makes the tone nasal and indistinct, and prevents the voice from "carrying."

These two palates may be called the sounding board of the voice, and the correct use of them is of the greatest importance. [2N]

The Uvula. At the back of the mouth, suspended from the middle of the soft palate may be seen a soft red piece of flesh about the size of the kernel of a hazel nut. This is the Uvula. It rises with the soft palate, and in some mouths seems to disappear altogether. Its work is to close the nasal passages, and so prevent the tone from becoming nasal. This does not, however, interfere at all with nasal resonance. [2O]



2. THE PHYSIOLOGY OF THE VOICE

The Teeth. No opportunity should be lost for impressing upon the student the great necessity for taking care of his teeth. Their work in singing is to help in the articulation of the consonants. A song becomes stupid and feeble when the consonants cannot be heard clearly and distinctly. The consonants, not the vowels, are the backbone of diction, and since the consonants are formed largely by the teeth, the care of the teeth is one of the first considerations in singing. [2P].

Classification of Voices. Generally speaking, human voices may be divided into two large classes, male and female. These are subdivided as follows:

MALE.

BASS. BARITONE. TENOR. ALTO, OR COUNTER-TENOR.

Basso Profondo. Basso Cantante. Tenor Robusto. Tenor Leggiero.

FEMALE.

CONTRALTO. MEZZO-SOPRANO. SOPRANO.

Soprano Drammatico. Soprano Leggiero.

The quality of the middle notes of a voice, not the compass, determines its classification.

The student cannot be too particular in grasping this fact.

During the first singing lesson it is often difficult for a teacher to classify a voice definitely. A number of lessons may be necessary before such decision can be made. For example, a student may come to him and sing a song of soprano compass with effect; but because she is able to sing the head notes in a soprano voice—even if the compass is high—it does not necessarily follow that she is a soprano. The tone and quality of her middle notes must be listened to carefully by the teacher ere he can decide.

The vocal cords of a bass and baritone are broader, thicker, and longer than those of a tenor and soprano. The *kind* of voice—soprano or contralto—is governed, therefore, chiefly by the size of the cords.

Although great similarity may exist, no two voices are quite alike; they differ in individuality as much as do faces, largely owing to the formation of the resonance chambers.

Compass. The compass of a voice is the range of sounds it is capable of producing, and these sounds are divided into registers. Each voice has three registers, which will be explained later. The table on this page shows the compass of the respective voices, but does not include voices of exceptional range.

Voice Characteristics. We must now consider the characteristics of the different voices.

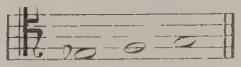
Basso Profondo. The Basso Profondo, which is the lowest male voice, is seldom met with nowadays. It is the fullest and deepest of all voices. Its chief characteristics are volume, intensity, richness, and broad phrasing; and its development is slow. There is always a great tendency to force, so the student must exercise much care and patience to avoid this fault, or the voice will become coarse. Another point to be carefully noted is the intonation. The vocal cords of a basso profondo are very thick, and in consequence the voice is particularly adapted to the sustained and declamatory styles of singing, but are, of course, quite unsuited for florid singing.

Basso Cantante. Although not so heavy, the Basso Cantante is more general than the basso profondo. Besides being lighter in quality, it has greater flexibility and a little higher range, as will be seen on reference to the compass. But, compared with the tenor and women's voices, it is deep and powerful. Its notes are capable of greater resonance than those of the baritone. The lowest notes, E, F, and F♯ in an untrained basso cantante voice may be weak, but with careful training they become full and rich.

Baritone. The Baritone in the classification of men's voices corresponds to the mezzo-soprano in women's voices, and partakes of some of the characteristics of both bass and tenor, with a greater resemblance to the former. It is capable of greater expression and modulation than the bass, besides being more flexible and mellow. It is the most general of all male voices. Although it does not possess the volume of the bass, it is fuller than the tenor. The great evil to be guarded against in the training of this voice is the tendency to shout and strain. The voice naturally is not the size of the bass, so the student must exercise great care not to force it or he will spoil the quality, and in time ruin the voice. The weakest notes of the baritone voice are the low A', A, and B.

Tenor. Of the male voices the Tenor is the highest. There are two kinds of tenor voices, the *Tenor Leggiero* or light tenor, and the *Tenor Robusto*, or full dramatic tenor. The volume and quality of these two varieties of tenor voices distinguish them from each other. The music for the tenor voice is usually written in the treble clef; it must be borne in mind, however, that the pitch of the notes actually sung by the tenor voice is an octave lower than that indicated. For example, the notes  when sung by a tenor are actually 
Originally, music for the tenor voice was written

in the tenor clef. The old clefs in singing are seldom used at the present. The above notes in the tenor clef would be written



Tenor Leggiero. The Tenor Leggiero, or light tenor, is noted for its brilliancy, lightness, and flexibility. The tone is most delightfully silvery, but wanting in sustaining power. It is, perhaps, the most difficult and delicate of all voices to train. It requires coaxing, then sweetness of tone and grace will result.

Tenor Robusto. The Tenor Robusto, or full dramatic tenor, like the basso profundo, is somewhat rare. It is full and rich, capable of great modulation, and can portray any passion necessary. The notes from F, first space, to B third line, are the most difficult to cultivate, and not infrequently are rather weak. Great care is necessary at the beginning of the training that the voice is not mistaken for a baritone. This is of the utmost importance, for if trained as a baritone, it will follow that the medium notes of the tenor are trained as baritone head notes, with disastrous results.

Alto. As a solo voice the Alto, or counter-tenor, is not very pleasing, but is useful as the highest voice in male part-songs and glees. It is most frequently met with in church choirs. Being an unnatural voice, very careful training is required.

Contralto. The Contralto is the fullest, deepest, and strongest of female voices, and is more capable of modulation and tender feeling than either the mezzo-soprano or soprano. Like the bass, it is not very flexible, and is particularly adapted to sustained and declamatory styles of singing. The weakest notes are from F, first space, to C, third space. Strict attention should be given to the cultivation of these notes during the first lessons, and special care must also be exercised to avoid forcing the chest notes, those from E, first line, down the scale.

With the majority of contraltos it is noticeable how weak are their medium, or middle, notes. This is due entirely to forcing the chest notes, which, when forced to any extent, become coarse and blatant, and produce, together with the weakened middle notes, the effect of two distinct voices.

The registers of contralto voices require the closest attention. Equality of tone is perhaps the most important feature to be developed in cultivating the contralto voice.

Mezzo-soprano. The Mezzo-soprano voice holds a similar position in female voices to that held by the baritone in male voices. It possesses some of the qualities of the contralto, notably fulness, mellowness, and roundness, being like the soprano inasmuch as it is capable of great flexibility. When perfect, it is often considered the most beautiful female voice; but it must be remembered that as it partakes of both contralto and soprano it must needs share the faults of both. Therefore, judgment and caution must be used in training to avoid its being taken too high or too low.

The greatest danger is that songs and exercises of too high a range are often sung by the mezzo-soprano, and if this practice is continued, the voice will be ruined. It is unadvisable, and often harmful, for a mezzo-soprano to sing contralto songs and exercises, although the result may not prove quite so disastrous as the singing of soprano songs.

At the beginning of study, let the middle notes be carefully trained, and the upper and lower notes develop naturally.

Generally, the weakest of all mezzo-soprano notes is E, fourth space

Soprano. The two kinds of soprano voices—the *Soprano Drammatico*, or dramatic soprano, and *Soprano Leggiero*, or light soprano—correspond almost exactly with the two kinds of tenor voices which have already been described. The soprano is the highest human voice. Because a woman's voice may be high in pitch, it is not necessarily a soprano—it may be a mezzo. The *quality* of the notes in every case decides the voice.

In training the soprano voice the tendency to overwork the highest notes must be strictly guarded against; if this injurious practice is continued, the tone will become weak, shrill, wiry, and thin.

The emphatic remarks made about the intelligent cultivation of the other voices previously noted apply with equal force to the light and dramatic soprano.

Respiration. It is of the utmost importance that before attempting to sing a note the student should try to acquire a correct method of respiration, or breath control.

The respiratory apparatus consists of the chest, thorax, and the respiratory tree (*arbre respiratoire*), which includes the larynx, the windpipe, the bronchi, and the lungs. The respiration of the animal kingdom is entirely opposite to that of the vegetable. In the former, oxygen is inhaled and carbonic acid exhaled; plants inhale or absorb carbonic acid and exhale oxygen.

Every human being and every animal from the moment of birth to that of death breathes; but very few of the former have naturally a correct method of respiration. It is essential that everyone, whether singers or not, should breathe in the manner intended by Nature. Unfortunately, civilisation, combined with the present mode of dress, has done much to hinder this. Savage races and the lower animals, whose bodily freedom is not impeded by clothing, breathe perfectly, because naturally.

The art of respiration comprises two movements—Inhalation or Inspiration, and Exhalation or expiration. With the former, life begins; with the latter, it ends. The average person inhales about 12 quarts of air per minute, 720 quarts per hour, 4,320 gallons per day The lungs, however, are capable of receiving seven times this amount.

Speaking of people in general, the quantity of air they draw in at each inspiration expands the

upper part of the lungs only; when the inspiration is *full*, the lungs expand at the base also.

The student's attention should be directed to the *muscles* controlling respiration, not to the lungs, which are passive. They of themselves cannot move or extend; it is the influx of air, together with the action of the muscles, that enlarge the lung space.

Exercises on the art of inspiration will follow. After the student has thoroughly mastered the art of inhalation, he may turn his attention to that of exhalation or expiration—the outflowing of the breath; but this must not be attempted too soon. Correct exhalation is even more difficult than correct inspiration.

Beauty of tone, phrasing, expression, duration, and so on depend entirely upon a correct mode of respiration.

Breath Management. Three methods of breath management are recognised: (1) diaphragmatic, (2) intercostal, and (3) clavicular; but the first, diaphragmatic, is the only correct method.

When diaphragmatic breathing is employed the lungs, which are fully inflated, press on the diaphragm [1F], and push it down on to the stomach, which in turn expands; at the same time, the outer intercostal muscles [1G] draw the ribs upwards and outwards, and in this way the cavity of the chest is considerably enlarged. The movements of these muscles are concomitant.

If the clothing is moderately loose, the diaphragm will work naturally, enabling the student to direct his whole attention to the movements of the rib muscles.

The shoulders should on no pretext whatever be raised during the act of respiration. Both the chest and stomach must expand whilst inhaling.

The second method necessitates the movement of the ribs only, which are raised and pushed out and the stomach slightly yet unconsciously drawn in, the diaphragm remaining stationary. Although frequently employed, this method is really insufficient, and often proves injurious.

The clavicular is decidedly incorrect; any student who understands the shape of the lungs and chest will perceive how pernicious it is, and abandon it at once. When this mode of breathing is practised, the diaphragm and the lower intercostal muscles are inactive, and their work is wrongly thrown upon the shoulders and collar-bone, which have to be raised and the muscles of the throat contracted to prevent the breath from rushing out from the upper parts of the lungs. The lower parts of the lungs in this method are never inflated. The column of air is shortened, and, in consequence, too great a pressure is put upon the vocal cords, setting up a hideous tremolo, which, if indulged in for any length, becomes incurable.

Some teachers of singing maintain that it is impossible for women to breathe diaphragmatically, an idea which is erroneous. It may not be possible for them to breathe so deeply as men—and owing to their structure there will always be a wider expansion of the chest—but with patient practice and perseverance every woman is able to breathe in this way.

To breathe diaphragmatically the body must be easy and natural. Both feet should be placed firmly on the ground, with one foot slightly forward bearing the full weight of the body. During practice it is advisable that the student should stand with his hands behind him, lightly resting them on the small of his back.

The shoulders must be kept back naturally and easily, and not be allowed to rise, the point of the shoulder being in a vertical line with the forward foot. When this position becomes strained the rear foot may be brought forward and the weight transferred to it. The chest must be well expanded, yet without drawing down the shoulders unnaturally. The muscles of the throat must be relaxed, the neck quite free and unconstrained, the head slightly forward and erect, not depressed, and the chin kept back, not pushed forward.

Let the mouth assume a smile so that the upper lip is slightly drawn off the teeth; also keep the tongue quite flat.

One of the commonest faults with beginners is the moving of the mouth and chin after the breath has been inhaled. This must be assiduously avoided by the student, who is recommended to practise before a mirror so as to guard against this bad habit.

Let the expression of the eyes be perfectly natural. Keep the eyebows still and the forehead smooth, as there must be no sign of effort or exertion whatsoever.

The following breathing exercises must be practised in pure air, not in a room where the air has been used up. They should never be practised when the body is fatigued, nor immediately after meals, because if the stomach is charged with food the diaphragm cannot work as it should. The best time to practise is in the morning whilst dressing, or about an hour and a half after breakfast. No tight clothing ought to be worn round neck or waist.

Although not absolutely essential, it is certainly advisable that both singers and speakers should keep their nostrils clean and free; this can be easily accomplished by using as a nose bath every morning a tumblerful of tepid water in which has been dissolved a tablespoonful of common salt. Pour a little of this into the hollow of the hand, and sniff it up the nostrils alternately three or four times. All foreign substances are removed in this way, and inhalation is greatly assisted.

Exercises for Inhalation. The first exercise is to inhale very slowly, quietly, and evenly through the mouth, which must be partly open to prevent the air passing through the nose. Place the hands lightly on each side of the body to feel the lower ribs expand. If pressed too heavily, the ribs will be prevented from moving to their fullest extent.

When the ribs are expanded to their utmost mentally count five, then let the breath rush out through the mouth. This ought to produce the sensation of the total collapse of the chest.

When five can be counted with great ease, increase the number to seven, nine, eleven, and thirteen. This exercise should be practised

twenty times a day, at four distinct intervals; it must never be practised twenty times in succession, as it is too fatiguing. It should be noted that the breath should be controlled by the diaphragm and rib muscles only.

To put it concisely, the exercise is this. Breathe slowly, quietly, and evenly through the mouth; hold the breath whilst mentally counting five; let the breath *rush* out through the mouth.

For a second exercise, inhale as in the previous exercise. Hold the breath whilst mentally counting three; re-inhale without allowing any of the first breath to escape; count one, then try and inhale again—that is, three inhalations in all—then let the breath rush out through the mouth. This must not be practised until the first exercise has been completely mastered. It must never be practised more than nine times a day at three distinct intervals. The object of this exercise is to increase the girth of the lower part of the chest.

The next exercise is to inhale through the mouth *quickly* and quietly, mentally counting five whilst holding the breath with the diaphragm and rib muscles; then let the breath *rush* out through the mouth. Gradually increase the number counted. Practise twenty times a day at four distinct intervals. It is possible that the student may make a gasping sound whilst inhaling quickly, but this can be avoided if the soft palate and uvula are raised. On no account must the shoulders be raised.

The fourth exercise is to inhale quickly and quietly. Count three, inhale; count one, inhale again; then let the breath rush out immediately through the mouth. Practise nine times a day at three distinct intervals. Should the sides of the mouth become dry, let the student inhale alternately through the nose and mouth.

Exercises for Exhalation. The first exhalation exercise is most generally used in songs, solfeggio, etc., when the breath has to be taken in hurriedly.

Inhale quickly and quietly through the mouth, hold the breath whilst mentally counting five, then let it pass out slowly and silently; keep the lower ribs expanded as long as possible, and feel that the stomach is very gradually inclining inwards and upwards. Be careful that the upper part of the chest does not move, and guard against puffing out the cheeks. Until the student becomes quite familiar with the movements required it is advisable that he should place one hand on his lower ribs and the other on his chest.

This exercise must not be attempted until the inhalation exercises have been thoroughly mastered. Practise fifteen times a day at three intervals. To express this briefly, take a *quick* quiet breath through the mouth, hold whilst mentally counting five, exhale very slowly.

A Difficult Exercise. We now come to the last exercise. It should always be used at the beginning of a song or solfeggio, or where a phrase is preceded by a rest. The remarks referring to exhalation in the first exercise apply equally to this. It requires very careful and diligent practice, or it will never be perfect.

Inhale slowly and silently through the mouth; mentally count five, and, by degrees, seven, nine, and eleven; exhale *very slowly*, keeping the ribs expanded till the last particle of air is expelled. This must not be practised more that nine times, at three distinct intervals, as it is very fatiguing.

All these exercises must be studied and persevered with in the above order to ensure complete mastery. When this has been accomplished, three of them must still be carefully and regularly practised every day, not only by the novice but also by the advanced student—inhalation, first exercise; exhalation, first exercise; exhalation, second exercise. They must be practised in this order.

Exhalation is controlled entirely by the diaphragm and rib muscles. The student must exert all his will power to prevent the rising of the former and the falling in of the latter after he has expanded the lungs by inhalation. It should be remembered that it is the will alone that can control their movements.

Another exercise of lesser importance, but beneficial to the student, is to inhale slowly, hold the breath whilst mentally counting five, then exhale slowly, counting *aloud* first as far as seven, then ten, increasing the number as he gains control over his breath. He may also recite the letters of the alphabet in the same way, but he must cease counting or reciting before the last particle of breath has expired or the end of the phrase will sound gaspy, and this will be quickly detected by a listener. It has been well said that by observing how a phrase is finished we can tell if the respiration is correct. MARY WILSON

Beet Sugar Growing and Manufacturing Processes. Minor Sources of Sugar. Refining Sugar. The Use of the Polariscope.

BEET SUGAR & ITS MANUFACTURE

SUGAR beet is grown in all the countries of Europe, from Sweden, in the north, to Spain, Italy, and Greece, in the south. It is cultivated in Canada and the United States, Australia, South Africa, Persia, and Siberia. The plant (*Beta vulgaris*) is indigenous to the South of Europe.

Propagation. Beet is propagated from seed. The original beet has been improved by a careful selection of the best sugar-bearers, and judicious and scientific fertilising has evolved beets which contain as much as 18 per cent. of sugar. Vilmorin of Paris was the pioneer in this work of selection, and his successors, Vilmorin, Andrieux & Co., are still recognised as the premier house for beet seed. In England the houses of Sutton and Carter have paid considerable attention to the production of a good sugar-bearing beet, and both sell a good seed suitable for growing in England. Beet giving a large sugar-yield costs no more to grow than beet with a small yield, so that the selection of seed is an important matter to the grower. Illustrations are given of the Vilmorin Improved, the White Silesian, from which the former is descended and sometimes regarded as a distinct species, and the Imperial [7]. Other well-known kinds are the Klein-Wanzleben and Heine's Vilmorin.

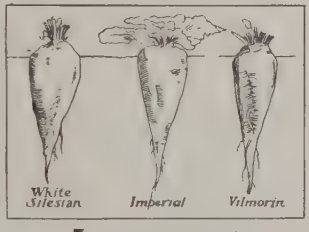
Characteristics of Good Beet. The shape and manner of growing of the beet are important. The most desired characteristics are thus summed up by Newlands :

1. Beets should have a regular, pear-shaped form and smooth skin.

2. They should not have a tendency to throw out forks or fingers and toes.

3. The flesh should be firm and white, the structure uniform, and the flavour "clean." Thin-skinned beets are preferable, as the thick-skinned varieties are frequently spongy and always more watery.

4. The beets should weigh 1½ lb. to 2½ lb. each, because neither very large nor very small roots are profitable to the manufacturer.



7. SUGAR BEETS

5. Good beets have no tendency to become "necky," and their tops are always smaller than those of inferior beets. The large-leaved are preferable to the small-leaved varieties.

6. Good beets are denser than water. The quantity of sugar can be roughly estimated by the density. If the beets sink in a liquid of 1·07 sp. gr., the percentage of sugar is about 14.

7. The roots should grow entirely in the ground in properly prepared soil.

Range of Temperature. Authorities are agreed that temperature has to be considered in beet cultivation, rather than the rainfall. Sugar formation is favourably influenced by dry weather in the autumn. A mean summer temperature of 70° F. for 90 days is sufficient to mature beetroot ; if the temperature be much above this the amount of sugar is diminished. The crop must be matured and safely harvested before the frosts set in.

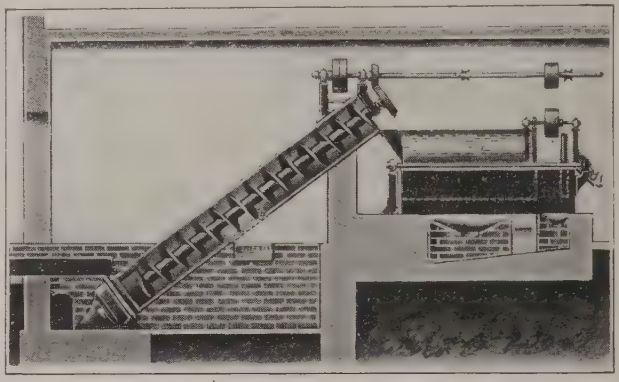
Soil. Any good soil that will grow wheat, and has an arable depth of 12 in. to 15 in., is well suited for beet culture ; it must be well drained. Where a large proportion of chalk is present in the soil, the juice yield of the beet is small but of good quality. In the United States, Dr. H. C. Meyers devoted much time to the study of the growth of beet in alkaline soil such as exists in Utah. Dr. Meyers found that moderate irrigation tends to carry the salts in the soil down to below the plant roots, and that by deep tillage, maintained throughout the season, evaporation and rising of the alkali may be largely prevented. The importance of these observations is that arid regions unsuitable for any other crop may be utilised for beet.

Sowing. In Great Britain, April is the time for sowing beet seed. The frosts should be over, because if the sowing be done too early and the plants become frost-bitten it will be necessary to plough up the first sowing and sow afresh. Some sow the seeds (previously soaked in water for 20 hours) in continuous lines along ridges which have been thrown up from 14 in. to 18 in. apart. The ground should have been stirred up to a depth of 12 in. by the cultivator or subsoil plough, and if manured the manure is ploughed in 5 in. deep. A better way than the continuous line is to dibble the seeds, three in each hole. To keep the beets down to the limits of size—½ lb. to 2½ lb.—they are planted with about 8 in. between the roots, bearing in mind that some of the new kinds of beet with strong foliage require the rows to be up to 20 in. apart instead of the 18 in. limit just referred to. The seedlings are allowed to grow until 3 in. to 4 in. high, and where more than one plant has come up from each hole the weakest are pulled up, and any misses filled up with these plants. The quantity of seed required, if sown in continuous line, is 10 lb. to 15 lb. an acre ; if dibbled in, 5 lb. to 7 lb.

Hoeing. As soon as the plants appear above the ground the soil should be kept loose and free from weeds by hand hoeing. After thinning and until the plants have grown too large, the horse hoe may be used two or three times, its work being finished off each time with a hand hoe. The soil should be earthed up so as to cover the roots. If any plants begin to send up stalks, the stalks should be at once broken off.

Harvesting. The crop must not be harvested until it is ripe, but at the same time it should not be left to be injured by the frost. In from three to seven months the leaves begin to droop and turn yellow, leaving exposed on the top of the root a crown of young green sprouts. As soon as this takes place, the roots are ready to be pulled. If the autumn be cold and dry, the roots

may be left without injury for a week or ten days later, but if the weather be mild and moist new growth would be encouraged, which is undesirable. The roots are pulled by hand labour, but more economically by special harvesters, consisting of a fork on wheels, drawn by horse power. The roots are caught by the prongs of the fork, which pulls them out of the ground and drops them. Care is taken not to puncture or bruise the roots, as this means loss of sugar. The earth is shaken off the roots, the leaves and crown are cut off [11], and the beets then carted to the factory.



8. SCREW CONVEYER FOR ELEVATING BEET

Use of Manures. The use of manure depends on the nature of the soil. It is generally recommended not to manure the beet crop directly, but to manure heavily a preceding cereal crop, and let the residue of manure serve for the beet. With modern artificial manures, however, the amount of manure can be adjusted to actual requirements, making it advantageous to manure the crop directly instead of indirectly. Nitrogenous compounds have a tendency to extend the period of growth and delay the time of ripening. This tendency must be corrected by phosphates. The Victorian Department of Agriculture recommend for light dressing 2 cwt. of sulphate of ammonia and ½ cwt. of superphosphate; for heavy dressing, 4 cwt. of sulphate of ammonia and 1½ cwt. of superphosphate per acre. Where potash is needed, ⅔ cwt. to 1½ cwt. of kainite may be used. The cost is heaviest the first year, because subsequently the refuse of the sugar factory is returned to the land, and goes a good way towards keeping the soil manured.

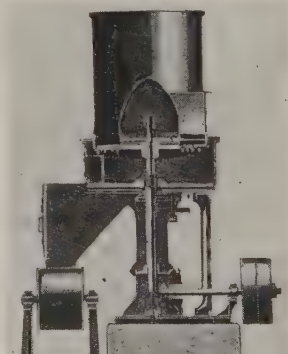
Stable manures must be used either on the preceding cereal crop or worked into the soil in the autumn ploughing. Chile saltpetre or nitrate of soda can be used in place of sulphate of ammonia, and the calcium nitrate produced electrolytically in Norway is equally efficient. [See page 307.]

Diseases. Beet is sometimes attacked by grubs of the beet canon-beetle (*Sulpha opaca*), the beet or mangold fly (*Anthomyia betæ*), and the silver moth (*Plusia gamma*). These are overcome by spraying the upper and under sides of the leaves with Paris-green solution. A disease known as "jaundice" is prevalent in the northern parts of France, and generally makes its appearance during the first fortnight in July. When the plant is first attacked the leaves begin to droop and become mottled with white translucent spots. It has been found that this is due to bacteria, and as the sugar yield is reduced by a half in diseased roots, the refuse from the crop should be burnt before being returned to the land. When stored in silos, a slight loss of sugar takes place, and "greying" of sugar has been directly traced to dry-rot which sometimes sets in during storage.

Yield of Beet. An acre of roots weighing 2 lb. each, and growing 10 in. apart in rows 15 in. apart, would, if there were no misses, yield 40½ tons of dressed roots. The heaviest yield has been 65 tons, and, while 25 to 35 tons may be reckoned as the average, this yield is high according to experimental growing in England.

Cultivation costs are difficult to give with accuracy, as conditions of labour and rents vary in different parts of the country. The average yield of washed roots which has been obtained in Norfolk and Suffolk is 12 tons per acre, and the total average cost of growing (including cultivation, seed, manure, rent and rates) comes out at £9 7s. 6d. per acre. At 25s. per ton (the price in 1914) a crop of 12 tons will give the farmer a return of £15, and a profit of £5 12s. 4d. per acre, less the cost of placing the crop on rail.

Yield of Sugar. The mean sugar content of 1200 samples of beet analysed by Graftian, a Belgian chemist, in 1898, was 16·4 per cent., the extremes being 20·2 and 12·5 per cent. About half the sugar is obtained as *first* sugars, the rest being divided between *second* sugars, *third* sugars, molasses, and losses. The average percentage of water in the beetroot is 77·69, and in the juice extracted 81·51, the average specific gravity of the juice being 1·077.



9. BEET SLICER

In 1879, a Select Committee of the House of Commons was appointed to inquire into the effect produced upon the home and colonial sugar industries of Great Britain by the bounty system in those countries which manufacture sugar for export. One of the witnesses, Mr. James Duncan, stated that Great Britain was adapted for beet cultivation, but that the bounty system of foreign countries, averaging £2 a ton, acted as a preventive of successful production of beet sugar in the British Isles. Dr. Voelcker, chemist to the Royal Agricultural Society, stated that he found 12 per cent. of sugar in roots grown in Suffolk; 12·5 to 13 per cent. in roots from Berkshire; 11·75 in roots from Surrey; 10·5 to 13·25 in roots from Yorkshire, and 10, 12, and 13, up to 15 per cent. in roots from Killarney. Mr. Martineau had roots grown in Lincolnshire and the Isle of Thanet, and obtained 15 per cent. of sugar, compared with the average (at that time) of 10·5 per cent. in France.

Experiments in Great Britain. The factory which Mr. Duncan started was at Lavenham, but the venture was not a success. The quality of the beets improved year by year, but the

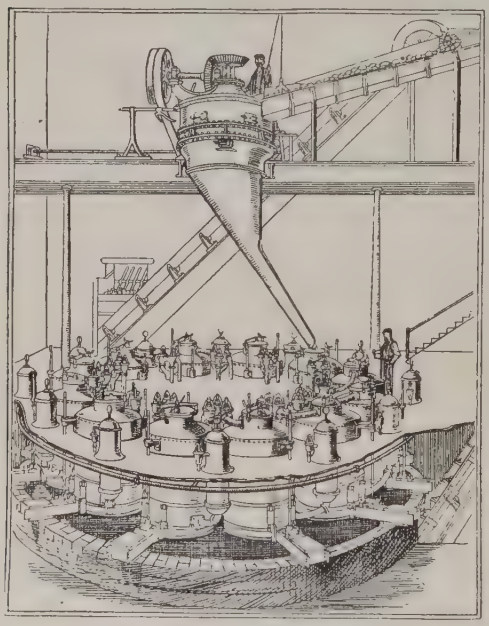
SUGAR BEETS IN ENGLAND AND FRANCE

10. ENGLISH-GROWN BEETROOTS. THOUSANDS OF TONS ON A FARM AT CANTLEY

11. REMOVING LEAVES AND CROWN FROM BEETROOTS DURING HARVESTING IN FRANCE

farmers did not properly modify their rotations to secure a sufficient supply of beets for working at a profit. Sir J. B. Lawes and Sir J. H. Gilbert published, in 1898, a valuable summary on the conclusions they had arrived at as to the growth and manufacture of sugar in the United Kingdom. On the whole, the authors were rather sceptical as to the suitability of England for beet-growing.

England Too Cold. The perfected beetroot grown abroad is supposed to require an average temperature of 70° F., while statistics show that the mean temperature for July, the hottest month in the year, is, in England, only 62·5° F., and for September and October 50° F. and 43·2° F. respectively. These latter are the critical months during which the beet matures and ripens, and, in England, October is nearly always rainy and often frosty. Norfolk or Suffolk they considered most suitable for beet cultivation, the climate being appropriate, and the soil neither too light nor too heavy.



12. CIRCULAR DIFFUSER

Why England should Grow Beet. The late Mr. Sigmund Stein, of Liverpool, for years advocated beet-growing in England. He enumerated the advantages which Great Britain possesses over Continental competitors. (1) We can grow more roots per acre; (2) we can grow richer roots than on the Continent; (3) we have the consumption at hand, since we are the greatest sugar consumers in the world; (4) we save freight; (5) we save commission, as the factory sells direct to the consumer; (6) we can make use of the latest improvements in cultivation and manufacture by having at our disposal the best implements and machinery; (7) we can manufacture refined sugar direct at a very low price; (8) we can employ the plant of our works in the summer months after the campaign is over much better than the factories can do on the Continent, as we have many other industries in this country which could be well carried out in this factory.

Profitable Home Cultivation. Since then experiments have been conducted on a large scale, and at Cantley, near Norwich [**10**], a factory has been built by the Anglo-Netherlands Sugar Corporation which, after uphill work, is now successful financially. The work is encouraged by the absence of any Excise duty on sugar to countervail the Customs duty. The question of the home cultivation became urgent in 1914, owing to the stoppage of supplies of sugar from Germany and Austria, and the production was urged of sugar within the Empire sufficient for the needs of the Empire.

From Beet to Beet Sugar. The outline for the process of manufacturing sugar from beet is as follows: The beets are washed from adhering earth and stones, and then, by means of an elevator, sent up to a machine which slices the beets into pieces resembling vermicelli. The slices are then put into large iron cylinders and "diffused" with hot water, by which means the sugar is obtained in solution. This sugar solution is then mixed with about 2 per cent. of lime, and carbonic acid gas passed into it. A chemical reaction takes place, and carbonate of lime is thrown to the bottom of the vessel, taking with it most of the impurities. The liming is repeated, and sulphurous acid gas passed in. Another precipitate then forms, and leaves a clear liquid, which is evaporated until sugar is thrown out in a similar way to that followed in the case of cane-sugar manufacture. The divisions into which the subject can conveniently be divided are: (1) washing and slicing, (2) diffusion, (3) saturation, (4) evaporation, and (5) crystallisation.

Raising the Beets to the Washers. The beets are conveyed to the washing tanks by bucket elevators, scoop-wheel elevators, or screw conveyers [**8**]. The *bucket* elevator is not much used—at least, in modern factories—as the grit and earth from the beetroot cause a disastrous amount of wear on the buckets and chains. The *scoop-wheel* consists of a long enclosed wheel, with a series of scoops on the circumference. The beets are conveyed down a channel to the bottom of the wheel, and are caught by the bottom scoop. The wheel of scoops revolves, and as each scoop takes up its quantity it passes higher up, and is replaced by the one behind it. When the scoops reach the top of the wheel their contents are automatically thrown into a channel which conveys them to the washing machine. To lift the beets to, say, 18 ft., the wheel requires to be very large and cumbrous; hence, if the distance be more than a few feet, the screw elevator is used. The *screw conveyer* is perhaps the most convenient means of transporting beets, and is also useful for lifting water at the same time. As will be seen from the illustration, the screw conveyer consists of a heavy hollow spindle with a spiral blade, the whole being placed in an inclined position. A screw conveyer about 40 in. diameter and 25 ft. long raises about 600 tons of beets in 24 hours.

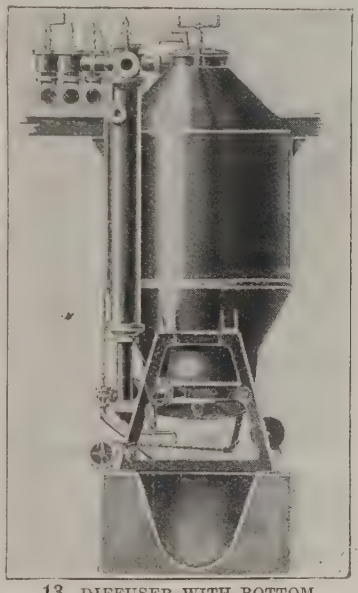
The Washing and Slicing Machines. Washing removes soil and pebbles, which would not only injure the slicers, but introduce much mineral impurity into the subsequent diffusing vessels. The simplest form of beet washer is known as the *whisk* washer. It is fitted with a stirring gear consisting of a central shaft to which vertical arms are attached. The vessel in which the stirring gear is attached is of wrought iron, open at the top, and fitted with a perforated bottom through which earth and stones fall. Underneath the

washing machine there is a discharge arrangement for the water, and the stone trap is fitted with a manhole for cleaning out the stones. Another form of washer consists of a perforated drum, into which the beets are put, and which revolves in a water trough fitted with discharge arrangements like the whisk machine.

After washing, the beets are conveyed by an elevator to the slicing machine on an upper floor. This elevator may be of the bucket variety, in which an endless chain of buckets is employed.

The slicing machines cut up the roots into *cossettes* or slices. A useful pattern is shown in **9**. Extra sets of cutter-boxes and knives should be ordered with the machine.

Diffusion. Formerly the beets were rasped to a pulp, the juice pressed out in hydraulic presses, and the solid mass dried by centrifugal machines. Schützenbach then suggested macerating the dried roots in warm water, but this comparatively slow process was replaced by the diffusion process, on the suggestion of Dubrunfaut. The sliced beet is conveyed to the diffusion battery by a band conveyer. Fig. **12** shows a battery in a series of twelve diffusers arranged in a circular manner, the one shown being fitted up by the Compagnie Fives-Lille. The hopper at the top revolves, and feeds the diffusers in turn with cossettes. Diffusion batteries are also arranged in straight lines of twelve or fourteen diffusers. The method of discharging the diffuser varies, but the bottom discharge for exhausted beets is preferable, as shown in **13**. Dr. Pfeiffer's patent discharge is effected by means of compressed air. As soon as one cell of the diffuser is charged with cossettes, it is shut down, and warm water run in. This water takes up some of the sugar, and is then passed into each of the other diffusers in turn. The smaller cylinders shown outside the circle of diffusers are called *calorisers*, and reheat the water, which, as it passes from the diffusers, loses much of its heat. The exhausted beet is discharged from the diffusers, and is conveyed to a pulp press, where a large proportion of the water is removed, and the residue left ready for cattle food.



13. DIFFUSER WITH BOTTOM DISCHARGE

Continuous Diffusion. In continuous diffusion the diffuser is an iron cylinder, and contains a perforated iron cylinder 4 ft. in diameter and 36 ft. long. The axis is formed by a smaller cylinder, and between the two is a helix. The inner cylinder is revolved at such a rate that beet slices travelling along the helix take about one hour to go the whole length. The cossettes are continually immersed in water, which enters at one end, at 86° F. The conditions for good diffusion are fulfilled when the cossettes and water move in opposite directions.

Saturation. The juice from the diffusers is conveyed to the saturation tanks, where 2 to 3 per cent. of lime is added in the form of milk of lime. The juice is then submitted to carbonic acid gas, this process being called *carbonatation*.

Double and Triple Carbonatation. The precipitate that falls takes down with it many of the impurities in the juice, and the heat that is applied sends up a scum. The clear liquid is decanted, the scums and sediment being filtered in a filter press. The clear juice is again treated with a smaller quantity of lime, carbonic acid gas passed in, and the resulting precipitate again removed. Finally, sulphurous acid gas is passed in, and the sulphide of lime removed by filtration. The clear liquid that results, known as "thin liquor," is next evaporated in a similar manner to cane juice. *Triple carbonatation* is sometimes used, but while it is of great value in practice, it is not considered sufficiently superior to double carbonatation to warrant general use.

Carbonic Acid Gas. The carbonic acid gas used in carbonatation is obtained by roasting limestone. The kilns in which this is done are either separately fired with coke or constructed to deal with coke and lime in alternate layers. The interiors of the kilns are built of firebrick and cased with iron plate. The carbonic acid gas is drawn off through two pipes near the top of the kiln, and the gas is then passed into a cooler and washer. The kilns are charged from the top with lime, or lime and coke. The gas washer is a cylindrical vessel; the gas enters near the bottom and meets a shower of water which falls from near the top of the washer. The gas finally leaves by an outlet at the top of the vessel to be pumped into the beet juice.

Sulphurous Acid Gas. Sulphurous acid gas is given off when sulphur is burnt in the air. It exerts a powerful bleaching effect on the beet juice. Special iron furnaces are made for generating the gas. Sulphur is fed in at the top, and combustion is started by inserting a red-hot iron, and kept up by passing in compressed air. The fumes known as sulphurous acid gas, are pumped direct into the beet juice at the stage indicated above. It is suggested that liquefied sulphurous acid might advantageously replace the gaseous form.

Use of Lime. The quicklime removed from the limekiln is used in the sugar factory for making milk of lime. This is usually done in brick tanks, but special lime-slaking machines are sold for the purpose. Sufficient water is used so that when all action has ceased the lime is still covered with water. Before being used more water is added to make milk of lime. Some workers recommend dry-slaked lime to be added to the beet juice instead of milk of lime, but others allege that darkening of the juice results from using the solid.

Saturation Plant. Carbonatation and sulphuration are carried on in square saturators, either sunk in the floor with working valves controlled from the top, or so arranged that the valves are in the front of the apparatus. The carbonic acid gas is admitted by valves, and there are also provided steam coil, inlet and outlet valves, and

juice valves. Saturation with sulphurous acid gas is conducted in similar saturators, which are connected with the gas supply from the sulphur furnace.

Filter Presses. The horizontal type of filter press, now so largely used, consists of a heavy cast-iron frame, supporting a number of square plates by means of projections on the sides of the plates. The square plates are corrugated on the surface, and upon each plate is placed a filter cloth. A series of these plates is screwed tight together by means of levers, and then the sugar juice is pumped or forced through the press by means of a central conduit. The pressure sends the clear juice through the cloths, leaving the sediment on the cloth in a cake. In another form of filter press now generally preferred the juice enters at the corner of the filter plates. Other types of filters are the Taylor filter [17], the Danek filter, which works at pressure, and the Claritas filter, which is designed for filtration without pressure. Sand filters should also be mentioned, as they are a cheap method of obtaining clear sugar juices.

14. COLLECTING MAPLE SAP

Special machines are made for washing the filter cloths. These consist of a cylinder in which is a revolving shaft carrying paddles.

Extraction of Sugar from Molasses. One of the most important problems in the sugar industry is how best to recover the sugar which remains in the molasses obtained in the manufacture of crystalline sugar from cane or beet. The process usually followed is that of Steffen.

The Steffen Process. Steffen discovered that lime forms with sugar three different saccharates—the *monobasic* saccharate, the *bibasic* saccharate, and the *tribasic* salt. The tribasic saccharate is with difficulty soluble in 200 parts of water, but is quite insoluble in water saturated with the tribasic salt itself. When precipitated under certain well-defined conditions it is granular, and can be readily washed in the filter. The operations in the process are: Forming the bibasic saccharate in the cold; boiling to form sugar and tribasic saccharate; and filtering the tribasic salt. The process is worked as follows: Molasses is diluted with water until it has a density of 6·6° Baumé, equal to from 7 to 8 per cent of sugar. Then, with constant agitation, small quantities of quicklime are added, in the proportion of 1 of lime to 1 of sugar. After each addition of quicklime the temperature rises, and is cooled to 15° C. before adding further portions of lime. The mixture is then filtered in a filter press, and the clear filtrate heated for ten minutes at 100° C. Tribasic saccharate is formed, and is filtered out and washed with hot water to decompose it. The residual lime is precipitated by passing carbonic acid gas into the solution, and the sugar obtained by filtering and evaporating. It is usual, however, to employ the tribasic saccharate instead of lime for treating raw juice. The other liquors are used for diluting further quantities of molasses, and are eventually used as a fertiliser when they become laden with the mineral impurities of the molasses. The Steffen process is equally applicable to the recovery of molasses in refineries, the slight variation involved being in the treatment of the saccharate. The saccharate from the presses passes into the dissolving pans, where it is dissolved by means of sugar syrup which has been saturated with carbonic acid gas and heated to about 70° C.; the sugar solution is then diluted with sweet waters so that it contains approximately 5 per cent. of sugar. After filtration the liquor is fully saturated with carbonic acid gas and treated as above. The processes of concentrating the sugar solution and "curing" the sugar are the same as those given for cane sugar.

Beet Sugar Factory. The cost of a factory for manufacturing beet sugar may be estimated at from £30,000 to £40,000, this sum providing the machinery for working 300 tons of beetroot a day. The factory building would take about a year to construct and fit, and would cost about £8000. A working capital of about £40,000 is also required for paying for roots and current expenses. Such a factory would purchase beetroots from the growers in the neighbourhood, or the beet-juice is conveyed from a distance by pipe lines. In regard to the general arrangement of the factory the ground floor is usually taken up with the beet-washing apparatus, the diffusion battery, centrifugals, vacuum pumps, beet elevators, boiler-house, limekiln, and bone-black filters. On the next floor are the carbonatation apparatus, the triple effet, upper part of diffusion apparatus, beet elevator, and laboratory, while on the upper floor are the vacuum pans. Rooms are provided for storing sugar and packing purposes.

15. SORGHUM

The Waste Products of Sugar Factories. The *bagasse* of cane-sugar factories is utilised as a fuel for generating motive power, and is also employed for paper-making, and as manure. Special furnaces are required for burning bagasse. Dry cane leaves (trash) are only slightly inferior to bagasse as fuel. Bagasse wet from the mill is commonly regarded as being equivalent in fuel value to from one-fifth to one-sixth of its weight in coal. Bagasse has also been proposed as a food for cattle.

Molasses is used as a fuel, for the manufacture of alcohol, and for feeding cattle. One method of using it as fuel is to sprinkle the molasses on the bagasse on its way to the furnace, or it can be sprayed on the burning bagasse. Animals take molasses fodder willingly, and no bad effect has been observed, or purgative action has been noted, and the quantity of milk in the cow fed on molasses fodder is increased, though it does not keep so well. Organic acids specially suited for mordanting wool have been made from *vinasse* or molasses residue.

Dried *diffusion pulp* from beet-sugar making should be dried before being used as a cattle food, otherwise it tends to bring on certain diseases. *Beet tops* are used for feeding cattle, or left to rot

in the field as manure. The *waste liquors* from beet-sugar factories have also been used as a source of ammonia.

MINOR SOURCES OF SUGAR

Palm Sugar. In India, besides the sugar cane, several palms are used as sources of sugar. The chief kinds are :

Palmyra palm or crab tree—botanical name, *Borassus flabelliformis.*

Indian date palm—botanical name, *Phœnix Sylvestris.*

Sago palm—botanical name, *Caryota urens.*

Coconut palm—botanical name, *Cocos nucifera.*

Neem tree—botanical name, *Melia azadirachta.*

The sap of these trees contains a good proportion of sugar, and it is this juice evaporated which forms the raw sugar. The sap is obtained from the Palmyra palm by slicing off the end of the flower stalk, and attaching to the stalk a little earthenware vessel to receive the sap. In the case of the date palm, incisions are made in the trunk at the place from which the lateral leaves have been removed.

Maple Sugar. Maple sugar is the produce of several kinds of maple-trees, the following being the chief varieties :

Sugar maple, hard maple, or rock maple—botanical names, *Acer barbatum, Michx., A. saccharinum Wang.*

Silver maple, soft maple, white maple, or swamp maple—botanical names, *A. saccharinum Linn, A. dasycarpum Ehrh.*

Red maple, soft maple, or swamp maple—botanical name, *A. rubrum Linn.*

Black maple—botanical names, *A. barbatum nigrum Sarg., A. saccharinum nigrum T. and G., A. nigrum Michx.*

Maple sugar and syrup are much prized in the countries of production—Canada and the United States—on account of their delicate flavour. The sugar is contained in the sap, and the trees are tapped from the middle of February to late in March. A hole three inches deep is bored into the trunk, and into this a tap is driven. The tap is provided with a hook, upon which is hung a bucket, as shown in the illustration [**14**], into which the sap flows. The process of obtaining sugar from maple sap is extremely simple, on account of its purity and freedom from extraneous matter. The contents of the sap buckets are emptied into a tank in the boiling "shop," and from this tank the sap is led to the evaporator, which is heated by prunings of the maple grove. If the maple sugar be required in the form of syrup, which saves much time and fuel, it is evaporated to a density of 1·325 or 11 lb. of sugar to the gallon, and poured while hot into perfectly clean pans or tins, which are then sealed to keep out the air. If made into sugar, the syrup is boiled over a brisk wood fire, in a pan smaller than the evaporator, to a concentration which will crystallise into sugar on cooling.

Sorghum Sugar. Broom corn, Chinese sugar cane, Imphee or Sorgho—botanical name, *Sorghum saccharatum Pers.*—is a graminaceous plant which has been the subject of much experiment as a sugar producer [**15**].

To obtain sugar from the sorghum, the stalks are passed through rollers, as in the case of the sugar cane. The juice is then limed, defecated, sulphured, and concentrated in much the same way as for Beet Sugar. Sorghum syrup is also prepared, in which case a little superphosphate of lime is added to the juice, to ensure a clear and brilliant syrup.

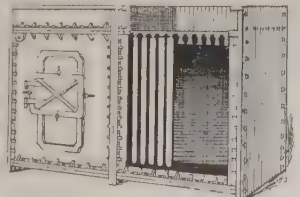
Maize Sugar. The stalks of Indian corn, *zea mays*, contain from 9 per cent. to 12 per cent. of sugar, and are used as a source of sugar.

Melon Sugar. Melons contain about 7 per cent. of sugar, and in California, where the melons grow prolifically on reclaimed land, syrup is produced in large quantities.

REFINING SUGAR

The term *refined sugar* is used for those finer qualities which are made from raw sugar, either cane or beet, at central refineries, and in which animal charcoal has been used for decolorising. Sugar refining is mainly a mechanical process, and consists, briefly, in dissolving the raw sugar in water, filtering through cloth to take out suspended matter, and then through animal charcoal to remove colour. The clear bright liquid is finally evaporated and boiled to crystallisation.

Preliminary Treatment. The raw sugar is usually submitted to a preliminary treatment before the first stage. It is mixed with a small quantity of syrup, put into a centrifugal apparatus, and washed with steam until the syrup flowing from the centrifuge comes away of a light colour. Raw sugar may be said to consist of sugar crystals and molasses, and by washing out the latter the purity of the sugar is at once raised by this treatment. The process separates the raw sugar into partly refined crystals and washings containing a good proportion of the molasses.



17. TAYLOR FILTER

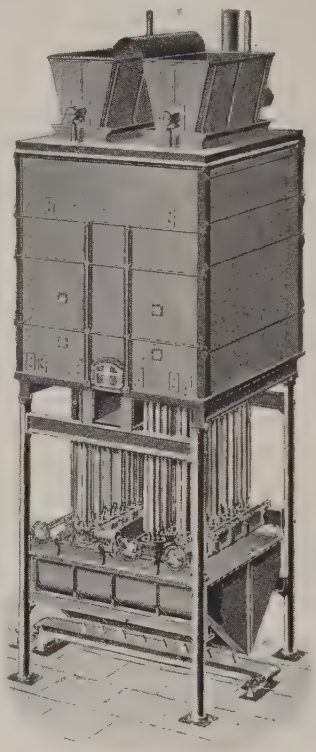
Melting. The partly refined sugar is dissolved in water, or, as it is termed, *melted*, the melting-pans, holding 3 tons to 10 tons, being known as *blow-ups*. The sugar is passed through a grating into the blow-up, which is provided with a false bottom, stirring gear, and heating arrangement either of copper coils or for live steam [**16**]. Here the sugar is melted at a temperature of

150° F. to 170° F. to a syrup of 28° Baumé, and is then filtered.

Filtration. Most refineries in Great Britain use the old Taylor bag or stocking filter [17] for clearing the liquor produced above, although the Danek filter is a favourite on the Continent. The filter presses described under Beet Sugar Manufacture are also used, but not to any great extent, as they are not so suitable for cane syrup. The Taylor filter consists of a large iron chamber with tightly fitting doors in the front. At the top is the tank or filter head, leading to a series of metal sockets to which long filter bags are attached. These bags are made of twilled cotton measuring 6 ft. long and 2 ft. to 3 ft. wide when opened out. The bags are put into sheaths of coarser material, and, the sheaths being smaller than the bags, a larger filtering surface is ensured. The bags are securely fastened on to the nozzles, and hang inside the chamber, which is fitted with steam heating appliances. A filter chamber contains 200 to 500 of the filter bags, and each bag can be separately controlled by plugging the hole leading to it from the filter head, this being necessary when one of the bags turns out to be defective.

The liquor from the blow-ups is run on to the filter head, and passes into the bags, the temperature being maintained by letting steam into the filter chamber. When the bags become blocked up with dirt the liquid ceases to pass, the supply of liquid is cut off, and the bags allowed to drain. The bags are then detached, and washed systematically in several tanks of warm water, the washings being reserved on account of the sugar they contain and run into the *sweet-water* tank.

Decoloration. From the Taylor filter the bright liquid is passed to large *char cisterns*. These are iron towers from 18 ft. to 50 ft. high, filled with animal charcoal or char. The bottom of the char cistern is a perforated plate covered with a blanket, and on this the char is packed to within a short distance of the top. The bright liquor, still warm, is allowed to flow in at the top, and, when full of liquid, the bottom cock is turned off and the whole left to "settle" for some hours. A char filter holding 20 tons of char has room, in addition, for about 10 tons of liquor. After a few hours the cock at the bottom is opened, and the liquor, now free from colour, drains away. More liquor is slowly introduced, until the filtrate becomes tinted, when the stream of liquid is passed into a separate vessel for a lower-grade product. This is continued until the colour shows that the char has ceased to work, when the supply of liquor at the top is cut off, and what remains in the char cistern drained off; the char is then washed with hot water, and the washings run into the sweet-water tank as long as they show the presence of notable quantities of sugar. The char is in this way washed till the water runs clear, when it is allowed to drain, and the char taken out and revivified by burning. In place of animal charcoal the use of new substances, such as "Eponite" and "Norit," has been proposed.



18. CHAR REVIVIFYING KILN
(J. Buchanan & Son, Liverpool)

Reburning Char. The revivification of the charcoal is effected in pipe kilns [18]. The *pipe kiln* consists of a series of cast-iron pipes into which the char is placed and heat applied to the outside of the pipes. The kilns are heated either by direct coke firing or by gas, the advantages of the latter method being that there is an economy of fuel, absence of ashes, and greater uniformity in heating. Beneath the kiln pipes are corresponding cooling pipes. The char is brought to the kilns wet, and is first dried and then, having been filled into the kiln pipes, is heated red hot. The char is next passed to the cooling pipes beneath by means of discharge valves, the contents of the cooling pipes being passed to a hopper, and from this taken to the char cistern for use again.

Boiling down is effected in the multiple-effet apparatus and vacuum pans which were described in the chapter on cane sugar manufacture.

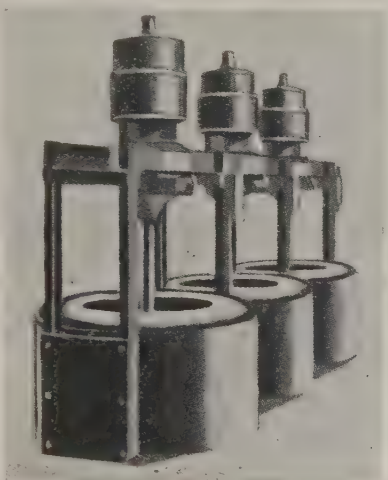
Crystallisation in Motion. In this method the massecuite from the pan is run into the apparatus, which takes the form of a large cylinder, and is kept in very slow movement by a stirring arrangement. In most cases hot water is circulated in the outer vessel to control the cooling, and in some cases the vessel is airtight and worked under a partial vacuum, air pressure being utilised to empty the pan when finished. The process prevents the formation of small grain by inducing the crystallisable parts of the massecuite to grow on crystals already formed or introduced. In the latter case the crystals are brought up to the temperature of the massecuite before being added. The advantage of having large crystals over small ones is that the separation of molasses in the centrifugal machines is much facilitated.

The method is used in beet-sugar manufacture as well as for residual products of the refinery.

Centrifugal Machines. When sugar is to be *machined* it is run from the vacuum pan into a heater fitted with stirring gear. From this it is placed into the baskets of centrifugal machines which, when revolved at a high speed, throw out the syrup. The sugar is more or less washed, discharged into bins, air dried, and packed in bags holding 2 cwt., for sale. The syrups and washings are collected separately; from the syrups another crop of crystals is obtained, while the washings, being purer, are boiled up with the liquors used for producing first product sugar. The centrifugal machine, also known as the *turbine*, to which reference has been made [19], is an apparatus which by water, belt, or electrical driving is spun at a rate varying from 500 to 1200 revolutions a minute. It is arranged for discharging the contents at the top or bottom, and has washing or steaming

appliances. Superheated steam is used in the Baker process. The basket into which the sugar is placed is made of perforated metal, the revolution of the basket causing the mass of crystals and molasses to be violently thrown against the inner wall; the molasses and a portion of the crystals pass through the perforations, but the greater part of the crystals are retained in the basket. Centrifugals are either driven or suspended, the latter type being used more. The size of the basket is 30 in. diameter, but a larger size of 48 in. diameter is in use which, although economising labour, takes more power to drive.

Loaf Sugar. The oldest form of refined sugar is the sugar loaf. To make these the massecuite is formed with a small grain, run into a heater and raised to between 180° and 190° F. From this the mass is run into conical iron moulds, which have a small hole at the top or cone, and a series of moulds is placed cone-downwards in a supporting frame. The hole at the bottom is stopped up with a wooden spike. When the sugar has been partly solidified the contents of the mould are mixed up with a "brushing off" hook with the object of making the texture throughout the loaf even. The moulds remain in the filling-house for 10 or 12 hours, and by that time the contents have become solid. Next, the moulds are removed to a warm room, the plugs in the cones removed, and "green" syrup drips from the mould for about 24 hours. A process known as *liquoring* then takes place. The top surface of the sugar is removed, mixed with syrup (*white liquor*, *cleare*, or *clairce*), and replaced. White liquor is then fed on to the top of the loaf and drains from the cone, taking with it any coloured impurities that remain in the sugar. The liquoring is repeated several times, blued water being used for the final liquoring until the runnings are quite clear and the loaves of uniform whiteness. The loaves are eventually taken out of the moulds, dried in racks, and wrapped up in thick paper. The process takes about a fortnight. The blued water referred to above is prepared from pure ultramarine, or a dye such as indanthrene blue, the purpose of the slight addition of blue being to correct any remaining tint of yellow.



19. CENTRIFUGAL MACHINES
(Watson, Laidlaw & Co., Glasgow)

Cube Sugar. The slowness of the method of making sugar loaves led inventors to study the question of how to make cube sugar in a quicker manner. Many inventions to this end, which involve similar principles, have been patented. The massecuite is boiled to small grain and filled into divided moulds of such a size that a plate of sugar is produced. The moulds are either a kind of centrifugal basket or contrived to fit into the centrifugal basket. The massecuite is cooled in the mould, during which process the crystals are joined together by a secondary crystallisation. The cooled moulds are then put in the centrifugal and the syrup spun out. The plates are also washed with clairce, which is in turn spun out. The moulds are removed and taken apart, the plates of sugar being separated and dried in a special store in a current of hot air. When the plates of sugar are dry, they are cut up into cubes in machines invented for the purpose. The Adant cube-sugar process is worked on the above lines.

Granulated Sugar. Granulated sugar is produced by the Hersey process, patented in 1873. The granulator consists of an outer conveyer cylinder 23 ft. long, 6 ft. diameter, inside which is a smaller cylinder 23 ft. long and 30 in. diameter, arranged to revolve about five times in a minute, and heated internally by steam. The granulator is inclined from the horizontal position, so that sugar introduced at one end travels mechanically to the lower end. A current of air is passed or driven through the drying chambers to absorb the moisture that arises from the sugar during its passage through the granulator. Sugar is first washed in a centrifuge, and then passed through the granulator, about 30 barrels of sugar being treated in an hour.

Other Methods of Refining. Alcohol was suggested for refining sugar by Duncan and Newlands as long ago as 1878, but the fiscal difficulties involved in the use of alcohol are insurmountable. In Langan's process the raw sugar is mixed with a saturated syrup so as to make a kind of artificial massecuite. The mass is drawn into a vacuum pan for the removal of small grain and any contained air. The mass is boiled to form a natural massecuite, then cooled in crystallisers to about 49° C., and subjected to a systematic washing and liquoring with saturated syrup to increase the purity. The sugar is then dissolved in the washing receptacle itself by means of a special appliance.

Fontenille & Desormeaux's Process. The Fontenille and Desormeaux process was patented in 1898, and is worked in the following stages:

1. Melt the raw sugar at a temperature of from 70° to 75°C. and at a density of about 28° Baumé.
2. Add finely powdered animal charcoal in the proportion of from 5 to 40 per cent. of the raw sugar, and mix at above temperature until the colour is discharged from the sugar.
3. Filter in press-filter, or separate the sugar in a centrifugal machine, the charcoal being recovered and washed.
4. Reheat the syrup to 75° C.
5. Pass the syrup through bag filters under pressure.
6. Concentrate and boil to grain.
7. Pass the massecuite into moulds or crystallising apparatus, or submit to centrifugal action. If poured into moulds, only one cleansing is required; if into a crystallising apparatus, the syrup is sucked away by the vacuum, and one cleansing only is needed. When the centrifugal method is used the mass is cleansed in the centrifuge.
8. The mass from the crystallising apparatus, or centrifuge, is broken up and sifted, and then sent to the moulding machine after moistening with 2 or 3 per cent. of blue water.
9. The moulding machine forms the pieces of the size required for sale by pressing. The pieces are expelled mechanically.

10. The pieces are dried in a store at 60° C., either in air or vacuum.

Crosfield and Stein's Process. The Crossfield and Stein process depends on the treatment of the acid solution of sugar with a bleaching agent known as peroxide of hydrogen.

The raw sugar is melted at about 160° F., and the acidity brought up to about 0·02 per cent. with phosphoric acid. The acid sugar liquor at about 27° Baumé, and at a temperature of 180° F., is treated with 0·01 to 1 per cent. of sulphate of alumina, and subsequently with 0·005 to 0·6 per cent. of tannic acid ; then with 0·05 to 0·2 per cent. of phosphoric acid, this treatment partly destroying the colour. Where deemed necessary the liquor may be treated with sulphurous acid. The liquor is next filtered, and the filtrate is treated with 0·01 to 1 per cent. of peroxide of hydrogen, and phosphate of soda or ammonia in quantities of about 0·005 to 0·2 per cent.

The liquor is passed through a filter press, and the clear, bright solution boiled to crystals in a vacuum pan. The massecuite, which is very white and bright, is machined in centrifugal machines and washed therein with concentrated syrup, or, if desired, sugar solution and peroxide of hydrogen.

Robin-Langlois Process. By the Robin-Langlois method the fibres and dust in the sugar are removed by blowing air across a stream of sugar falling from a hopper on to a series of inclined boards. The sugar is then crushed and treated with steam in order to introduce a definite small proportion of moisture, and to brighten the facets of the small crystals. This operation is performed in the mixer for the sake of uniformity. Jets of steam or atomised water impinge against angle plates, whence they rebound on to the sugar, falling from the supply tube into the mixer in two streams.

The *mixer* is essentially an annular space between two concentric hot-water jackets, the rotating blades and sugar being contained in this space at a desired high temperature. The discharge hole of the mixer stands above an annular trough in a revolving circular table, the circumference of the two machines intersecting to the necessary extent.

The circular table contains on its periphery a trough across which the moulds are arranged radially in juxtaposed boxes. These moulds are open at the top, and have perforated bottoms. They are locked, disengaged, and opened by special appliances which enable them to work continuously and to be emptied without injury to the bars of sugar. As the annular series of moulds revolve, they pass in turn under the discharge hole of the mixer, and are filled with sugar by inclined scrapers ; they then pass on, and the sugar in each mould is compressed by a corrugated roller fixed in relation to the table, but revolving on its own axis, so that its projections correspond consecutively with each mould. At a further stage of the revolution the moulds are automatically placed under vacuum and the syrup sucked out, and when dry they are unlocked, emptied, and readjusted continuously by the devices mentioned above.

In the La Fontaine method the patentee applies the reducing agent—sulphurous acid—to the massecuite instead of the raw juice.

And in the Ranson process the syrup is made alkaline with barium hydrate or sodium carbonate, and hydrogen peroxide added in the proportion of from ½ litre to 5 litres per 100 kilos of sugar, according to the colour of the product.

Treacle and Golden Syrup. When the syrups no longer yield sugar they are made into treacle, golden syrup, or invert sugar. Golden syrup is a purer kind of treacle. Of late years the quality has much improved, the appearance in many cases being artificially improved by the addition of glucose syrup. Glucose syrup is also used to prevent granulation, but, in the opinion of some experts, is not necessary if the sugar syrup be well inverted, which is done by treating it with acid.

SUGAR ANALYSIS

The chief analytical operations required deal with the density of juices and syrups, the amount of sugar in a given sample of sugar, the proportion of glucose or uncrystallisable sugar, the moisture, the soluble and insoluble ash, and the rendement.

Density. Density is conveniently taken by means of an instrument known as a *hydrometer* [see pages 611 and 613], the method in which a specific-gravity bottle is employed being too lengthy for general use. The two hydrometers in ordinary use are the Baumé and the Brix, or Balling. The latter is preferred, as the graduations of the scale give close approximations to the percentage of total solids present ; 10° Brix, for example, in a clean juice indicates 10 per cent. of sugar.

Schmidt and Haensch's Polariscope. The amount of sugar in raw sugar is determined by the *polariscope* [see page 2718], the degree of polarisation being the basis upon which sugar is bought and Customs duty levied.

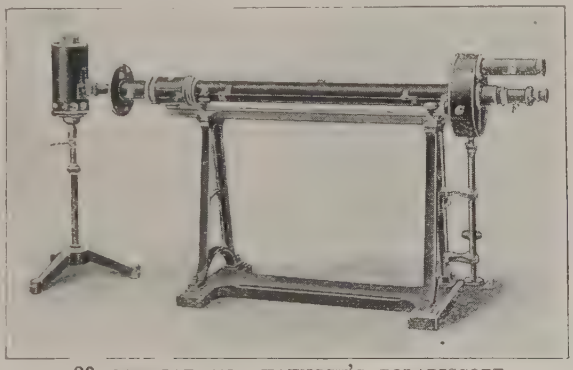
Of the several types of polariscope the *half-shadow* instrument is the one preferred. The principal feature of this type is the division of the circular field of vision into two halves. When the vernier is placed at zero the two halves of the field are uniform in shade. If an observation tube be filled with an optically active liquid, such as a solution of sugar, and placed between the polariser and analyser, the equilibrium is destroyed, the result being that one half of the field becomes dark and the other half bright ; the analyser is then turned to the right of the right half beshaded, or to the left of the left half beshaded, until the field is once more of a uniform shade ; the rotation is then read from the scale.

The form of polariscope or saccharimeter in use in the British Customs Department and the United States Internal Revenue Bureau is that of Schmidt and Haensch [**20**]. This instrument is adapted for use with white light illumination from coal-gas. It is convenient and easy to read, requiring no delicate discrimination of colours by the observer. It is adjusted to the Ventzke scale, which may be defined as "such that the degree of the scale is one-hundredth part of the rotation produced in the plane of polarisation of white light in a column 200 mm. long by a standard solution of chemically pure sucrose at 17·5° C., the standard length of the sucrose in distilled water being such as to contain at 17·5° C. in 100 Mohr's c.c. 26·048 grammes of sucrose." The instrument should be adjusted by means of control quartz plates, three different plates being used for comparative adjustments, reading approximately 100, 90, and 80 degrees on the scale respectively.

A Description of the Polariscope. The illustration [**20**] shows the best form of this polariscope. The tube B contains the illuminating system of lenses ; the polarising prism is at P, and the analysing prism at G. F carries a small telescope, through which the field of the instrument is viewed, and just above is the reading tube M, which is provided with a mirror and magnifying lens for reading the scale. The tube containing the sugar solution is marked R To

use the instrument the operator seats himself with his eye level with the tube F, which tube is moved in and out until the proper focus is secured so as to give a clearly defined image, when the field of the instrument will appear as a red luminous disc, divided into two halves by a vertical line passing through the centre, and darker on one half of the disc than on the other. If, now, the milled head A be rotated first one way and then the other, the appearance of the field changes, and at a certain point the dark half becomes light and the light half dark. By rotating the milled head delicately backwards and forwards over this point, the exact position when the field is neutral or of the same intensity of light in both halves can be found. When the milled head is set at the point which gives the appearance of the centre disc in figure the eye of the observer is raised to the reading tube M, and the position on the scale noted. On each side of the zero line of the vernier a space corresponding to nine divisions of the movable scale is divided into ten equal parts, enabling fractional parts of a degree to be indicated.

Method of Manipulation. Begin by weighing out 26·048 grammes of sugar, dissolving it, clarifying the solution, making it up to standard volume (100 c.c.), and filtering and filling the observation tube, regulating the illumination and making the polariscope reading. The sugar is conveniently weighed in a counterpoised nickel flask with a large lip, whence it is readily washed into the flask. The solution, before being filled up to the mark, is clarified by the addition of lead subacetate or phospho-tungstic acid until no further precipitate takes place. Filtration and clarification may often be made easier by adding a few drops of suspended aluminic hydrate after the lead. The flask is filled with pure water until the lower line of the meniscus coincides with the mark on the neck. The mouth of the flask is closed and its contents well shaken and poured on to a folded filter; the first few cubic centimetres of the filtrate are rejected. The subsequent filtrate, if not perfectly clear, is returned to the filter until it shows no cloudiness. The polariscope tube is then filled and placed in the polariscope, the scale of which, after neutralising the rotation produced by the sugar by turning the analytical prism of moving the quartz wedge, will give the percentage of sucrose in the sample taken. A dark solution may either be read in a 100 mm. tube or decolorised by bone-black. A weak solution may be read in a longer tube.



20. SCHMIDT AND HAENSCH'S POLARISCOPE

Estimation of Glucose. The reagent required for estimating reducing sugar is known as *Fehling's solution*. Take 34·64 grammes of pure crystallised sulphate of copper, and dissolve it in 200 c.c. of distilled water. Also take 187 grammes of tartrate of soda and potash and 78 grammes of caustic soda, and dissolve in 500 c.c. of distilled water. Add the copper solution to the second solution, and make up to 1000 c.c. with distilled water. The copper in 10 c.c. of this solution is completely reduced by 0·05 gramme of glucose, which is shown by the blue copper solution turning red and throwing down a precipitate of red copper oxide. To make the estimation, place 10 c.c. of the Fehling solution in a flask over a Bunsen burner, and make it boil. Then from a graduated tube (burette) run in a few cubic centimetres of the sugar solution, again boil, and note if any blue colour remain in the liquid. If there be some blue liquid over the red precipitate, run in more sugar solution until all the blue colour has disappeared. From the number of cubic centimetres of sugar solution required, the amount of glucose is determined by calculation. The best results are obtained when not less than 10 c.c. or more than 50 c.c. of sugar solution are needed for 100 c.c. of Fehling solution, and after making a rough estimation the strength of the solution is adjusted to conform with these requirements. The strength of the copper solution can be checked or standardised by comparing it with a solution of pure invert sugar, prepared by heating cane-sugar solution, with a few drops of sulphuric acid to invert it.

Moisture. Weigh from two to five grammes of the sugar into a flat-bottomed nickel or platinum dish, and dry at a temperature of 100° C. for three hours. Cool in a desiccator and weigh: return to the oven and dry for an hour. If, on weighing, there be only a slight change in weight, the process may be considered finished; otherwise the drying must be continued until the loss of water in one hour is not greater than 0·20 per cent. From the quantity of loss of weight of the sample taken the amount of moisture or water is calculated.

Ash. Take five or ten grammes of sugar in a platinum dish, heat at 100° C. until the water is expelled to allow the action to take place slowly, and finally heat in a muffle to low redness. Then, by weighing the ash that is left, the percentage of ash in the sample is obtained. The quantity of soluble ash is estimated by digesting the ash with water, filtering through a Gooch crucible, washing with hot water, drying the residue at 100° C., and weighing. The difference in weight from the above determination equals the soluble ash.

Rendement. Rendement is the French term for the net amount of sugar in a given sample of raw sugar. It is deduced from the fact that each 1 per cent. of ash in the raw sugar prevents 5 per cent. of sugar from crystallising, and each 1 per cent. of glucose causes an equal amount of sugar to be retained in the molasses. Hence, from the amount of sucrose shown by the polarimeter deduct five times the weight of ash plus the weight of the glucose present, and the refining value or rendement is obtained. For instance, a sample of sugar polarised 93 per cent., the glucose was 2 per cent. and the ash 1 per cent., $93 - (1 \times 5 + 2) = 86$ per cent. of available sugar.

There are many alternative methods of analysing sugar, but the above processes are representative of those employed commercially.

Designs of Pulleys, Rope Wheels, Gears and Gear Teeth, Chains, Cones, and Clutches.

DRAWINGS FOR PULLEYS AND GEARS

Pulleys. Pulleys are made either of cast iron, mild steel, or wood. Cast-iron pulleys may have straight arms, as **73**, single curved arms, as **74**, or double curved arms, as **83**; sectional views are given in **84** and **85**. The object in making the arms curved is to ensure a safe casting, since a straight arm does not yield so readily to accommodate the unequal contraction of rim and boss when the casting cools. The usual section of pulley arm is oval, as **86**, and it tapers from the boss to the rim. The forces acting on the arms tend to break them off, as in the case of the railway axle. The bending movement is found by multiplying the driving force on the rim of the pulley by the radial length of the arm, and dividing by the number of arms. The modulus of an oval section is $= \frac{3{\cdot}1416}{32} \times BA^2$, where A is the depth and B is the width of the section, and a safe stress for cast-iron pulleys is 2000 lb. per square inch. Pulleys are, to a large extent, standard articles, and are manufactured for stock; consequently they are made to cover a wide range of loads. The number of arms may be four for pulleys up to say, 24 in. diameter, and six for pulleys above 24 in. Looking at the sections **84** and **85**, single arms are used up to 12 in. wide and double arms up to 20 in. wide. The length of the boss may be one and a half to two and a half times the diameter of the shaft, while the thickness may be ·45 times the diameter of the shaft; the boss and the inside of the rim should taper slightly, in order to facilitate moulding. The rim of a pulley is slightly rounded, as shown in **87**. A belt will run on a *flat-faced* pulley, but is safer when running on a *convex surface;* flat-faced pulleys are used in cases where the belt is to be moved sideways from a fast pulley to a loose one, as in **88**, which represents a common device used for starting and stopping countershafts in connection with machine tools, etc.

Wrought-iron and Steel Pulleys. A wrought-iron pulley, shown in **78**, **79**, and **80**, is built in halves, and consists of a cast-iron boss and wrought-iron or steel arms and rim. The boss may be cast with the arms placed in position in the mould, or, alternatively, the latter may be screwed and tapped into the boss; the outer ends of the arms have solid collars, and are cold-riveted into the rim; a joint plate is fitted where the half rims meet. Cast-iron pulleys are also made in halves in a similar manner, but flanges are cast under the rims instead of using joint plates. The number of arms in a wrought-iron pulley varies from six to twelve, according to diameter and thickness of rim; double arms [**78**] are used with this class of pulley when a width of 9 in. is exceeded; the diameter of the arm varies from $\frac{1}{2}$ in. to $\frac{7}{8}$ in. These pulleys are generally made with a flat rim, but they can be machined to a convex surface.

A pressed-steel pulley has the arms and rim cold-pressed into shape from steel plates; the arms are dished in cross section, in order to give side stiffness, and also at the end, where they are attached to the boss in order to relieve the rivets from shearing forces. An interlocking plate is riveted between the arms, where they are attached to the rim; this plate enters the rim and so helps the two outer rivets. The rim is curved on the face, and is formed with the edges bent round so as to combine stiffness with lightness; in some cases the rim is doubled on itself, so as to give a specially strong rim for extra heavy duty. The boss and rim are in halves, and are bolted together.

Relative Speeds of Pulleys. A belt may not only be regarded as an agent for the transmission of power, but also as a means of giving a certain speed to a shaft. Taking the case of a belt drive where both pulleys have the same diameter, as **89**, it is evident that both shafts will revolve at the same speed if "slip" is neglected; but if it be desired to drive one shaft at twice the speed of the other, then one of the pulleys must be twice the diameter of the other; the circumferential speed of both pulleys remains the same, but the smaller one, having half the circumferential length of the other, makes two revolutions to the other's one. The following rules may be deduced from the above principle:

To find the diameter of a driven pulley to give a certain speed to a shaft, the diameter and speed of the driving pulley being known.

Rule: Multiply the diameter of the driving pulley by its speed in revolutions per minute, and divide the result by the required speed of the driven shaft in revolutions per minute.

To find the speed of a driven shaft, having the diameters of both pulleys given as well as the speed of the driver.

Rule: Multiply the diameter of the driving pulley by its speed in revolutions per minute, and divide the result by the diameter of the driven pulley.

To find the diameter of a driving pulley, the diameter of the driven pulley and the speeds of both being given.

Rule: Multiply the diameter of the driven pulley by its speed in revolutions per minute, and divide the result by the speed of the driving shaft in revolutions per minute.

Fig. **90**, together with the following calculations, illustrates the above rules:

$$\text{Diameter of driven pulley} = \frac{36 \times 150}{270} = 20 \text{ in.}$$

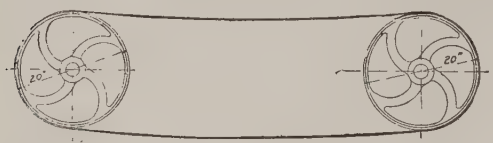
$$\text{Speed of driven shaft} = \frac{36 \times 150}{20} = 270 \text{ r.p.m.}$$

$$\text{Diameter of driving pulley} = \frac{20 \times 270}{150} = 36 \text{ in.}$$

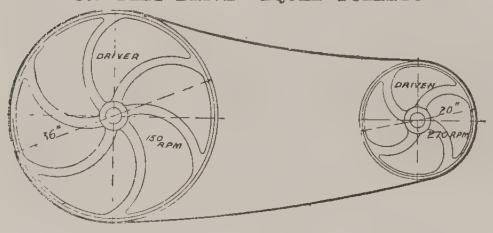
The thickness of the belt affects the calculations to a slight extent, because the true belt-speed should be measured on the centre line of the belt; when a belt bends round a pulley its inner surface is compressed and its outer surface is extended, but the centre line remains unaltered, and is consequently the theoretical driving line. The difference is not very appreciable with single belts and medium velocity ratios, but in speeding up from a slow-running shaft to a high-speed fan or dynamo, it may upset the calculation to the extent of 3 per cent., or even 5 per cent.

Speed Cones. When it is desired to drive a machine at various speeds from a shaft running at a constant speed, it is usual to employ speed cones as illustrated in **91**; they are arranged opposite each other, so that the smallest pulley of one set is abreast of the largest one of the other set; the added diameters of any two pulleys abreast of each other is a constant; that is, $A+C'=B+B'=C+A'$; the driving belt can then be readily slipped from one set to another, and the speed of the driven set altered accordingly. Assuming the shaft D to be the driver, and to be running at 150 revolutions per minute, then when the belt is on A and C′ as shown [**91**], the speed of shaft E is $\frac{150 \times 6}{12} = 75$ r.p.m.; when the belt is on B and B′ the speed of shaft E is $\frac{150 \times 9}{9} = 150$ r.p.m.; when the belt is on C and A′ the speed of E is $\frac{150 \times 12}{6} = 300$ r.p.m. The section of the cones is shown dotted; there are no arms except when the large cone is of a considerable diameter, or when there are a great number of steps; a boss and arms are then arranged to support it, as shown in **75**.

Open and Crossed Belts. Open and crossed belts are used on planing machines, screw-



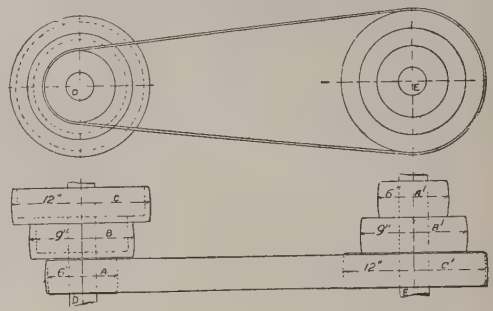
89. BELT DRIVE—EQUAL PULLEYS



90. BELT DRIVE—UNEQUAL PULLEYS

cutting lathes, etc., for the purpose of reversing the motion of a shaft after a certain operation has terminated. A typical example occurs in **92**, where A is the driving-pulley, B, C, and D are driven pulleys, B and D being keyed on their shaft and C running loose; the "open" belt is marked E and the "crossed" belt is marked F. Suitable striking gear is arranged to move both belts sideways at the same moment; when the belts are in the position shown [**92**], the open belt is driving the pulley B in the direction of the arrow G, whilst the crossed belt is driving the loose pulley only; upon striking the belts the open one drives the loose pulley and the crossed one pulley D, but in a reverse direction.

Rope Driving. Cotton and hemp ropes are used for the transmission of power in a similar manner to belts, but usually for main drives only. The textile mills of Lancashire afford numerous examples of direct rope-driving from main engine shafts to line shafts on the various floors, the fly-wheel itself doing duty as the driving pulley. Ropes are made by twisting three "strands" together in a right-hand direction; each strand is formed of "yarns" twisted together in a left-hand direction, the yarns themselves being spun from cotton or hemp fibres in a right-hand direction. The diameter of the finished rope varies from $\frac{3}{4}$ in. to 2 in.; the sizes in most frequent use are $1\frac{1}{4}$ in. to $1\frac{3}{4}$ in. diameter. The ultimate or breaking strength of a rope ranges between 7000 lb. and 11,000 lb. per

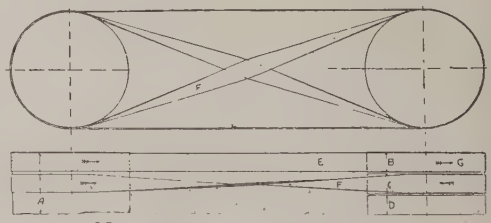


91. SPEED CONES

square inch. The safe working load is, however, only taken at 140 lb. per square inch, or, say, $\frac{1}{10}$ of the average breaking load; and unless this large factor of safety be allowed, the life of the rope is short. A main driving rope should last from five to eight years. The stress of 140 lb. per square inch does not represent the actual stress upon the fibres of the rope, but only that on the driving side due to the power transmitted. In addition to this, the rope has to sustain forces due to the wedging of the rope in the grooves of the pulleys, and also the stress due to centrifugal action. This latter stress increases as the square of the speed of the rope—that is, if the speed be doubled, the tension on the rope due to centrifugal force is increased four times, and if trebled is increased nine times; a speed is soon reached beyond which it is not economical to go, because the strength of the rope would be wasted in overcoming this force, instead of transmitting power. The highest economical speed lies between 4000 ft. and 5000 ft. per minute, and at this speed the effective load on the rope is about 200 lb. per square inch, instead of the 140 lb. per square inch due to the driving tension of the power which is transmitted.

Powers of Rope. At 4800 ft. per minute the powers which various ropes can transmit are as follows:

$\frac{3}{4}$ in. rope	= $8\frac{3}{4}$ h.p.	$1\frac{3}{8}$ in. rope	= 29 h.p.
$\frac{7}{8}$ " "	= $11\frac{3}{4}$ "	$1\frac{1}{2}$ " "	= $34\frac{3}{4}$ "
1 " "	= $15\frac{1}{2}$ "	$1\frac{5}{8}$ " "	= $40\frac{3}{4}$ "
$1\frac{1}{8}$ " "	= $19\frac{1}{2}$ "	$1\frac{3}{4}$ " "	= $47\frac{1}{4}$ "
$1\frac{1}{4}$ " "	= 24 "	2 " "	= $61\frac{3}{4}$ "



92. OPEN AND CROSSED BELT

These figures represent the maximum powers to be obtained from ropes at any speed whatever; further increase of speed does not result in an increased horse-power transmitted, but, on the contrary, it steadily declines, until at 8000 ft. per

minute the rope can barely withstand the centrifugal forces alone. Below 4800 ft. per minute the power transmitted, of course, decreases, but not in exact ratio of speed, because, as the speed becomes less, so the centrifugal forces decrease; at half the above speed—namely, 2400 ft. per minute—the following powers can be transmitted:

$\frac{3}{4}$ in. rope	= 6 h.p.	$1\frac{3}{8}$ in. rope	= 20 h.p.
$\frac{7}{8}$ " "	= 8 "	$1\frac{1}{2}$ " "	= 24 "
1 " "	= $10\frac{1}{2}$ "	$1\frac{5}{8}$ " "	= 28 "
$1\frac{1}{8}$ " "	= $13\frac{1}{2}$ "	$1\frac{3}{4}$ " "	= $32\frac{1}{2}$ "
$1\frac{1}{4}$ " "	= $16\frac{1}{2}$ "	2 " "	= $42\frac{1}{2}$ "

Since the capacity of a single rope is limited to a comparatively small horse-power, it is necessary to use a number of ropes on one pulley in order to transmit the required power, which may amount to several thousand horse-power in some cases. Small engines have from 3 to 10 ropes, larger ones 10 to 30, whilst some engines have been fitted with wheels having 50 and even 60 ropes.

Rope Wheels. The wheels are usually of cast iron and have machined grooves in the rim as shown in **72**, the proportions of which are given in the table. The diameter of a rope pulley should not be less than 30 times the diameter of the rope, otherwise the life of the rope is shortened by constant bending on too small a diameter. Rope pulley arms are usually oval in section, and may be calculated in the manner described for belt pulleys. Rope pulleys are, however, more carefully designed and manufactured, on account of their weight and of the higher speeds at which they run. Main driving pulleys on an engine frequently attain the enormous weight of 70 or 80 tons apiece. They are built up of a number of separate castings, the

ROPE GROOVES FOR PULLEYS

boss is in two parts, machined and bolted together, the arms are separate and are cast hollow, cottared into the boss and bolted to the rim; the rim is in segments, faced up and bolted or cottared together. Such pulleys are made from 20 ft. to 34 ft. diameter; smaller ones down to 12 ft. diameter are made in halves, but the rims are frequently built up in segments; from 12 ft. to 8 ft. diameter they are simply made in halves, whilst 8 ft. pulleys are cast in one piece. The object in building up the larger sizes is to ensure a wheel free from initial stress due to contraction; the stresses arising from centrifugal action alone when such heavy masses are moving at a high speed are very considerable, and, in fact, it is not wise or safe to exceed 5000 ft. per minute with a cast-iron rim. Heavy wheel rims have been known to burst at 4500 ft. per minute. As the design of rope-driving pulleys is closely allied to flywheel design, it is more fully discussed under that heading in a later chapter.

Arrangements of Ropes. There are two methods of arranging the ropes for a given drive. The usual plan adopted in England and on the Continent is to use a separate rope for each groove in the pulley, the ropes being spliced to as nearly the same length as possible. In America a different arrangement is extensively employed; a single rope is wound continuously in a spiral round the pulleys, and is made to pass over a weighted pulley, which gives a certain tension to the ropes; by such means it is ensured that each rope element is taking its share of the drive. A great disadvantage of this method is that if the rope breaks the whole drive is at a standstill, and in all probability the rope becomes so entangled that a serious loss of time occurs before it can be got clear and a new rope reeved on.

Wherever possible, the driving side of the rope should occur underneath; then the sag of the slack or top side increases the arc of contact, and so adds to the efficiency of the drive. The length of a rope drive—that is, the distance from centre to centre of the pulleys—should be as great as possible—from 20 ft. up to 80 ft. or 100 ft.; it is best to arrange it horizontally, or at most at an angle of 45 degrees. The sag of a rope follows a curve termed a "catenary," which approximates a parabola, and this latter curve may be used when drawing out a rope drive to determine clearances. Single-rope drives are used occasionally for special machinery and for overhead travellers; the ropes are then small in diameter, in order to keep the pulleys down to a convenient size.

Toothed Gears. We have seen that a belt or a rope does not transmit power accurately, but that a certain loss of speed occurs, due to "slip." Toothed gears are not open to this objection, and are accordingly employed where motion has to be transmitted accurately. Another advantage accrues from their use, and that is that they are much more economical of space than belts or ropes. The simplest form of toothed gear is shown in **82**, and is termed *spur gear* or *spur and pinion*. The larger of the two wheels is the spur wheel and the smaller one is the pinion. The term *pinion* is applied somewhat loosely in practice, but is generally understood to mean the smaller of any two wheels in contact, or any wheel having less than twenty teeth.

The dotted circles marked A are the *pitch lines* or *pitch circles;* these are the theoretical lines of contact, and from them measurements are taken. The pitch of the teeth, B, is the distance from the centre of one tooth to the centre of the next one. When measuring a wheel it is convenient to take the pitch from the edges of the teeth, as B^1. That portion of the tooth, C, which extends above the pitch line is termed the *face* or *addendum;* while that portion, D, which lies below the pitch line is called the *flank* or *dedendum*. The extreme outer end, E, of the tooth is the *point*, and the lower end, F, is the *root*.

Forms of Teeth. The forms of the teeth of gear-wheels have occupied the attention of engineers to a very considerable extent; an ideal gear would have a constant motion identical with that of two smooth-faced pulleys whose diameter would represent the pitch circles in contact. If the tooth form does not permit this constant velocity at the pitch line, then a more or less noisy and inefficient gear results. A badly formed tooth is contributory to what is called *backlash*. A variation in velocity causes relative movement between the

teeth in gear, and they leave their driving faces and come into collision with the teeth in front of them, the amount of the backlash being equal to the clearance between the teeth.

There are two forms of teeth generally adopted—namely, *double curve* or *cycloidal*, and *single curve* or *involute*. The double curve tooth is shown in **76**, and the single curve tooth in **77**.

A method of striking out the double curve tooth is indicated in **81**. AB is the pitch circle, whose centre is at C. Upon it roll two circles, D and E, termed *generating circles*. The outer one, D, describes the outer or *epicycloid* curve; the inner one, E, describes the inner or *hypocycloid* curve. The diameter of each circle may be taken at twice the pitch. Taking the outer circle first, mark it out in a number of equidistant positions as shown, and draw the centre lines through to C; then take the arcs F G, F H, F I, F J, F K, and F L, and step round similar arcs on the generating circle in its various positions so that G M is equal to G F, H N is equal to H F, I O is equal to I F, J P is equal to J F, K Q is equal to K F, and L R is equal to L F, remembering always that the curved line or arc must be measured, and not a straight line or chord. Through the points M, N, O, P, Q, and R lies the true path of the *epicycloid* curve. The *hypocycloid* is obtained in a similar manner, with the inner generating circle rolling in the reverse direction. Only a portion of the curve is required for a tooth, as shown in hatched lines. The diameter of the generating circle has great influence on the thickness of the tooth at the root and at the point; if it were made of equal diameter to the radius of the pitch circle the flanks of the teeth would be radial straight lines. Now, the same generating circle which is used for a wheel must also be used for any wheel or pinion which has to gear with it; therefore the diameter of a generating circle is limited to the radius of the smallest pinion of any set of wheels gearing together, otherwise the teeth would be less in thickness at the root than at the pitch line, and the strength of the pinion would be reduced. The recognised limit for the lowest number of teeth in a pinion is 12, but 11, 10, and even 9 teeth are not uncommon on cranes and winches. Taking, however, 12 teeth as the minimum in average practice, the diameter of the generating circle works out to practically twice the pitch.

The Odontograph. The odontograph is an instrument invented to avoid the labour of marking out the cycloidal curves for each and every size of wheel and pinion that may be required. Suitable radii are given upon the instrument for the faces and flanks of teeth for all ordinary numbers. One of its edges is cut to an angle of 75°, which can be laid in certain definite positions relatively to the pitch and pitch line, and so used in order to obtain the centres of the radii.

The depth of wheel teeth is quite independent of the tooth curves; and it may be noted here that there is at present a distinct tendency to use shorter teeth than formerly; this tendency takes effect in machine-cut gears (which are described later), and would undoubtedly obtain in ordinary cast gear but for the confusion that would arise in many engineers' shops through interference with existing practice. Cycloidal and involute curves are theoretical lines, and do not vary, but tooth proportions are arbitrary, and are determined by trial and error in actual practice. For instance, in **81** it will be seen that the length of the tooth can be varied without affecting its true curve; naturally, a short tooth will carry a greater load than a long one in an inverse proportion to its length; the tooth itself is no stronger, but the length of the cantilever is less. Working conditions demand teeth of sufficient length to ensure good contact even when wheels are not set accurately and the pitch circles do not coincide. In dealing with gears to transmit great power, it is usual to design the teeth specially, and then the length of the tooth may be reduced to ·5 of the pitch, or even less.

Single-curve Teeth. The method of constructing the involute curve of a *single-curve tooth* is shown in **93**, where A B is the pitch line. First mark off the equidistant points D E F G H, and from each point draw a tangent to the curve; then set off the distance D I equal to the arc D C, E J equal to E C, F K equal to F C, G L equal to G C, H M equal to H C, and a curve drawn through the points I J K L M will be the involute required. It is, in effect, a curve formed by the unwinding of a cord from the arc of the circle.

An approximation sufficiently correct for practical purposes is to strike the curve with a radius equal to one-fourth of the radius of the pitch circle. Fig. **94** shows how this is arranged. A semicircle, A, is drawn on the radius of the pitch circle, and the centre, B, is located upon it; a dotted circle is drawn through the point as a *base circle* for striking the curves of the other teeth. This construction has, however, to be slightly modified when dealing with wheels having less than 30 teeth. The flanks have then to be made parallel with each other for certain distances, the amount of which is arbitrary, and depends upon the number of teeth.

Double-curve Teeth. The relative advantages of single and double curve teeth is a very much discussed question, and one which is by no means settled. The practice in England has been for many years distinctly in favour of double-curve teeth, due, no doubt, to the wide adoption of the odontograph instrument, together with an exaggerated idea of the theory that single-curve teeth cause undue pressure upon the shaft bearings. The tendency at present is to adopt the single curve universally, and this has been brought about largely by the introduction of *machine-cut* gears.

When toothed gears of a very fine pitch are required, it has been the practice to cut the tooth spaces from a solid rim, in order to attain sufficient accuracy to ensure quiet running. It has been left to Messrs. Brown & Sharpe, of America, to develop this idea, and to standardise the forms and proportions of machine-cut gears of all sizes and pitches. The Brown & Sharpe involute gear cutters are now used regularly all over the world, and are as much recognised as a standard article as the Whitworth and the Sellers screw threads are in their sphere. Gears having cast teeth are, of course, still widely used, but for all accurate and high-speed work cut gear has the monopoly.

Diametral Pitch. The base of calculation for cut gears is the *diametral pitch*. When drawing wheel teeth on paper, or when constructing a pattern, it is convenient and natural to measure the pitch of the teeth on the circumference of the pitch circle, and such a measurement it termed *circular pitch*. Now, when dealing with cut gears, this method of measurement disappears. The pattern-maker is not concerned with the spacing of the teeth—he simply has to prepare a wheel blank of a certain *diameter*; the machinist has to turn the blank casting to the correct *diameter*, and the gear-cutting machine is set to cut a certain number of teeth.

Consequently, circumferential measurements by rule or compass are not required in the process of manufacture. Therefore, the pitch is spoken of in terms of the diameter instead of the circumference of the wheel.

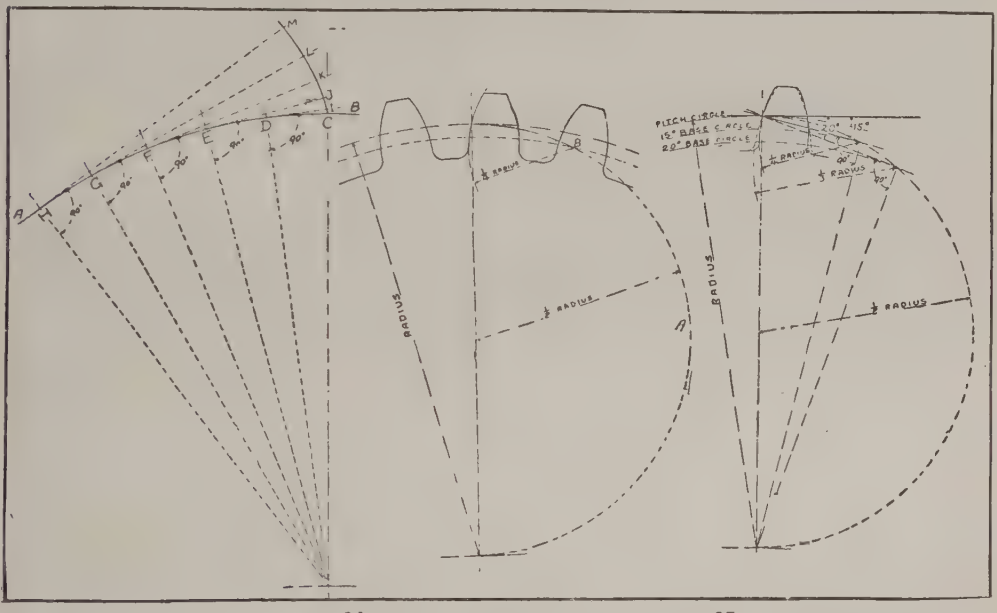
If the circumference of a pitch circle be divided by the number of teeth in the wheel, the result will be "circular pitch." In the same manner, if the diameter of the pitch circle be divided by the number of teeth, the result will be "diameter pitch." The *diametral pitch* is the reciprocal of diameter pitch. The *reciprocal* of a number is 1 divided by that number. Thus, the reciprocal of 4 is $\frac{1}{4}$, because $\frac{1}{4}$ will divide into 1 four times. Now, if we take a wheel having 48 teeth and a pitch diameter of 12 in., the diameter pitch is $\frac{12}{48} = \frac{1}{4}$ in., and the diametral pitch is $1 \div \frac{1}{4}$ in. $= 4$. In other words, diametral pitch is the number of teeth per inch of diameter of pitch circle; this idea may be a little

the number of teeth, and divide by the wheel diameter (convert to decimals):

$$\frac{60+2}{20{\cdot}66} = 3 \text{ diametral pitch.}$$

Relation of Diametral Pitch to Circular Pitch. The relation of diametral to circular pitch is the relation of the diameter of a circle to its circumference, which equals 3·1416. To obtain the equivalent circular pitch from a diametral pitch, divide the latter into 3·1416. Example: Required the equivalent circular pitch to 5 diametral pitch: $\frac{3{\cdot}1416}{5} = {\cdot}6283$ circular pitch. Conversely, required the equivalent diametral pitch to $1\frac{1}{2}$ in. circular pitch: $\frac{3{\cdot}1416}{1{\cdot}5} = 2{\cdot}0944$ diametral pitch.

A table is given on the next page showing the equivalent circular pitches for diametral pitches from 1 to 50. The Brown & Sharpe involute teeth



93. INVOLUTE CURVE **94.** MARKING OUT AN INVOLUTE TOOTH **95.** ANGLE OF OBLIQUITY

difficult to grasp at first, but the following calculations will show the simplicity of its application:

To find the pitch diameter of a wheel having, say, 94 teeth of 3 diametral pitch: Divide the number of teeth by the diametral pitch:

$$\frac{94}{3} = 31{\cdot}33 \text{ in.} = 31\tfrac{1}{3}\tfrac{1}{2} \text{ in. pitch diameter.}$$

To find the diameter of a wheel blank to cut, say, 94 teeth of 3 diametral pitch: Add 2 to the number of teeth and divide by the diametral pitch: $\frac{94+2}{3} = 32$ in. diameter of blank, or *whole diameter of wheel*, as it is sometimes termed.

To find the diametral pitch of a wheel having, say, 60 teeth, and of 24 in. diameter: Divide the number of teeth by the diameter of the pitch circle: $\frac{60}{24} = 2\frac{1}{2}$ diametral pitch.

To find the diametral pitch of a wheel, say, $20\frac{2}{3}\frac{1}{2}$ in. whole diameter, and having 60 teeth: Add 2 to

may be set out generally as described for **94**, the proportions being as follows:

Height of tooth from pitch line, ·3183 circular pitch. Width of tooth on pitch line, ·5 circular pitch. Depth of tooth below pitch line, ·3683 circular pitch.

Tooth Proportions. The following gives the standard proportions, although the practice in recent years has been to shorten the teeth.

CIRCULAR PITCHES. Having the numbers of teeth given, to find distance between centres: Multiply half the sum of the teeth by the circular pitch, and divide by 3·1416.

To find pitch diameter: Multiply the number of teeth by the circular pitch, and divide by 3·1416. Or multiply by 0·3183.

To find the number of teeth: Multiply the pitch diameter by 3·1416, and divide by the circular pitch.

To find outside diameter: The number of teeth

plus 2 is multiplied by the circular pitch, and divided by 3·1416; or multiplied by 0·3183.

To find thickness of tooth at the pitch line: Divide the pitch by 2.

To find the whole depth of tooth: Multiply the circular pitch by 0·6866.

To obtain the working depth of tooth: Multiply the circular pitch by 0·6366.

To obtain the bottom clearance: Multiply the circular pitch by 0·05.

Diametral Pitches. Having the number of teeth given, to find distance between centres: Divide half the sum of the teeth of both gears by the diametral pitch.

To find pitch diameter: Divide the number of teeth by the diametral pitch.

To find the number of teeth: Multiply the pitch diameter by the pitch.

To find outside diameter: Add 2 to the number of teeth, and divide by the pitch.

To find thickness of tooth at the pitch line: Divide 1·5708 by the diametral pitch.

To find the whole depth of tooth: Divide 2·157 by the diametral pitch.

To obtain bottom clearance: Divide 0·157 by the diametral pitch.

Strength of Spur Teeth. The strength of spur-wheel teeth may be calculated upon two bases: the one by considering a static load to be sustained by the tooth, and the other by considering the horse-power to be transmitted. For slow-moving machinery, it is convenient to estimate the load which comes on the wheel teeth, and to assume that this load is applied at the point of one tooth; the case is then treated as a simple cantilever loaded at the outer end. If the teeth are badly made, or if the wheels are not properly adjusted on the shafts, the load may come on one corner of the tooth instead of being distributed evenly across the face. Many formulæ in use deliberately assume such to be the case in ordinary work, but with modern machine-moulded or machine-cut gears there is no necessity to make such provision. The number of teeth in gear at the same moment will make a difference to the carrying capacity of a wheel; with large wheels of fine pitch gearing together, several teeth will divide the load between them; but if a small pinion be geared with a wheel, the full load may easily come on one tooth only.

Properly speaking, each individual case should be investigated and designed accordingly. Having determined the load which the tooth must carry, multiply that load by the full depth of the tooth for a bending moment; the modulus of a rectangle is $\frac{B H^2}{6}$ where B is the breadth or face of the tooth, and H is the thickness at the root; multiplying the modulus by the safe stress per square inch gives the moment of resistance of the tooth, which should be equal and opposite to the bending moment. A safe stress for cast iron is 3000 lb. per square in., and 10,000 lb. per square in. for cast steel. [See the table given below.]

The thickness at the root of an odontograph tooth varies from ·4 to ·6 of the circular pitch when ranging from 15 to 60 teeth. The breadth or face of a toothed wheel may vary from one and a half to three times the circular pitch.

There are 40 to 50 different rules in existence for the calculation of the horse-power which may be transmitted by toothed gearing, the majority of them depending upon an arbitrary factor which covers allowances for inaccurate workmanship and stresses due to centrifugal action. A safe rule is $HP = \frac{D P F N}{1000}$, where D = pitch diameter of wheel in inches, P = circular pitch, F = face of wheel in inches, N = speed of wheel in revolutions per minute.

TABLE OF DIAMETRAL AND CIRCULAR PITCHES

Diametral Pitch	Circular Pitch	Diametral Pitch	Circular Pitch

The Wilfred Lewis Formula. This is used largely in connection with machine-cut gear. It was introduced by Mr. Wilfred Lewis at Philadelphia, U.S.A., in 1893. He assumes that the whole load is taken upon one tooth, and that the tooth is a cantilever loaded at one end. From a consideration of various sizes of involute and cycloidal gears he selects the weakest cross-section of each, and determines its relation to the pitch; then from these data deduces the formula W = S P F Y, where W is the load transmitted in pounds, S is the safe working stress per square

SAFE WORKING STRESSES FOR DIFFERENT SPEEDS

Speed of Teeth in feet per Minute.	100 or Less	200	300	600	900	1,200	1,800	2,400

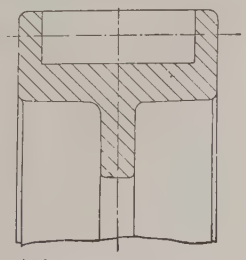
99. HALF SHROUDED TOOTH



100. FULL SHROUDED TOOTH

inch in pounds, P is the circular pitch, F is the face of the tooth in inches, and Y is a factor varying with the shape and number of teeth. The values of Y and S are given in the table on page 5646.

It will be noticed in the table that the involute is given as 20° and 15° obliquity; the angle of obliquity is measured between a horizontal line cutting the pitch circles at their point of contact and a line drawn perpendicular to the curve of the tooth, and being a tangent to the base circle. Fig. **95** shows the effect on the thickness of the tooth due to an alteration in the angle of obliquity; the greater the angle, the stronger the tooth. A 20° obliquity gives a tooth radius of about one-third the pitch circle radius.

When drawing gears to be cut with Brown & Sharpe cutters the angle of 15° may be taken.

Arms of Spur Wheels. These are made oval section [**96**], cross section [**97**], or H section [**98**]. The first-mentioned is used for comparatively light machine-cut gears, the second is used chiefly for gear wheels moulded from patterns, the third is adopted for machine-moulded wheels and for large and heavy gears. Frequently machine-cut gears are made with solid web plates without arms. The strength of a wheel arm may be calculated in the same way that we dealt with pulley arms. For the cross arm section the following proportions give good results:

Thickness of rim (A) = ·46 circular pitch
Width of arm (B) = circular pitch × 2
Depth of rib (C) = circular pitch
Thickness of arm (D) = ·43 circular pitch
Thickness of arm (E) = ·5 circular pitch
Thickness of boss (F) = $\frac{1}{3}$ of shaft diameter + $\frac{1}{4}$ in.

The above dimensions apply at the centre of the arms, the taper being about $\frac{3}{4}$ in. per foot either way. The number of arms in a wheel may be taken as:

Up to 1 ft. 6 in. diameter .. .. .. 4 arms
Up to 8 ft. diameter .. .. 6 arms
Above 8 ft. diameter .. .. 8 arms

The proportions for H arms may be taken as follows:

Thickness of rim (A) = ·375 circular pitch
Depth of rib (B) = A + ·01 pitch diameter
Width of arm (C) = circular pitch + ·035 pitch diameter
Thickness of web (D) = ·375 circular pitch
Thickness of flange (E) = $\frac{1}{8}$ of breadth of tooth
Thickness of boss (F) = $\frac{1}{3}$ of shaft diameter + $\frac{1}{4}$ in.

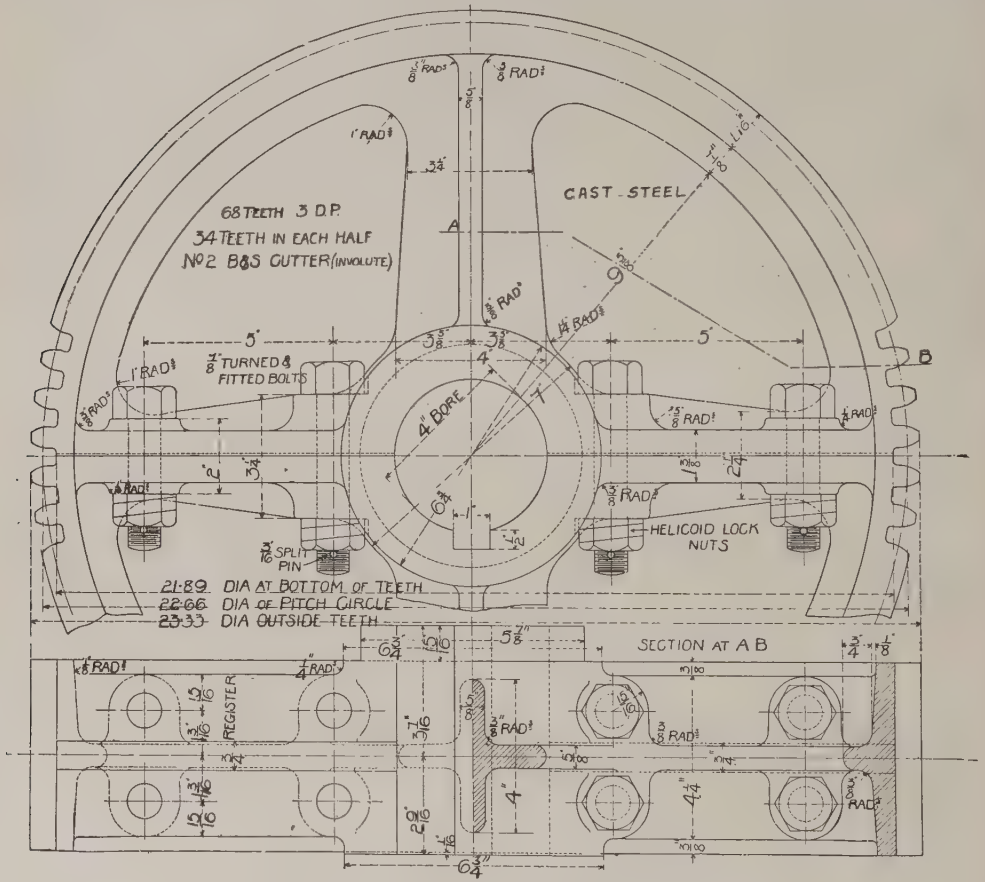
The remarks concerning the taper and the number of arms for the cross section arms apply equally to H arms. It will be noticed that in the cross and H section arms the face of the wheel is slightly wider than the width of the arms, this giving a better appearance to the wheel than if both were flush, and in the case of machine-cut gear it facilitates the machining of the sides.

Cast gears are frequently shrouded up to the pitch circle as **99**, full shrouded as **100**, or shrouded partially, or wholly on one side only; this adds from 20 to 50 per cent. to the strength of the gear. A common device is to shroud a pinion, but not the wheel it gears with, this being done to compensate for the unequal strength of the teeth at their roots. The thickness of the shroud may be one-third of the circular pitch.

Split Gears. Sometimes gear wheels are made in halves for convenience of renewal. A typical example is given in **101**, which represents a working drawing of a *split spur wheel* for an electric tramcar axle. It is necessary both for

railway and tramway rolling stock to force the running wheels upon the axles with sufficient pressure to ensure their rigidity when negotiating a curve at high speed, for if a wheel then slipped sideways upon its axle the vehicle would be instantly derailed. Now, when the wheels are so securely fastened to an axle, it is very important that anything between them shall be removable without disturbing them, and hence the dividing of the driving spur, which is keyed to the axle between the two running wheels.

Looking at the drawing **101**, it will be noticed that a groove is planed across the joint of one half to receive a register formed on the other half.



101. SPLIT GEAR WHEEL FOR ELECTRIC TRAMCAR AXLE

This relieves the bolts from shearing forces while the teeth are being cut, and also from side pressures should they occur when running. Note the section cut on A B joined by a diagonal line for the convenience of showing two sections not strictly in the same plane. In wheels of this nature it is necessary to see that they contain an even number of teeth, so as to divide properly without parting a tooth at the joint. There is no necessity to show all the teeth on the drawing. In the data given on the drawing for cutting the teeth, D P, of course, means diametral pitch, whilst the reference to No. 2 B. & S. cutter means a Brown & Sharpe involute cutter No. 2.

Large spur wheels are built up in a similar manner to that described for large rope wheels, and chiefly for the same reasons. Gear teeth are also formed upon the rims of flywheels.

Speeds of Wheels. The relative speeds of gear wheels may be calculated in the same way as in the case of belt pulleys by using the pitch circle diameters, except that there is no loss due to slip. We may, however, simplify the calculations by using the number of teeth contained in a wheel instead of its pitch diameter. This is useful when cut gears are involved, as their pitch diameters may run into vulgar fractions or decimals.

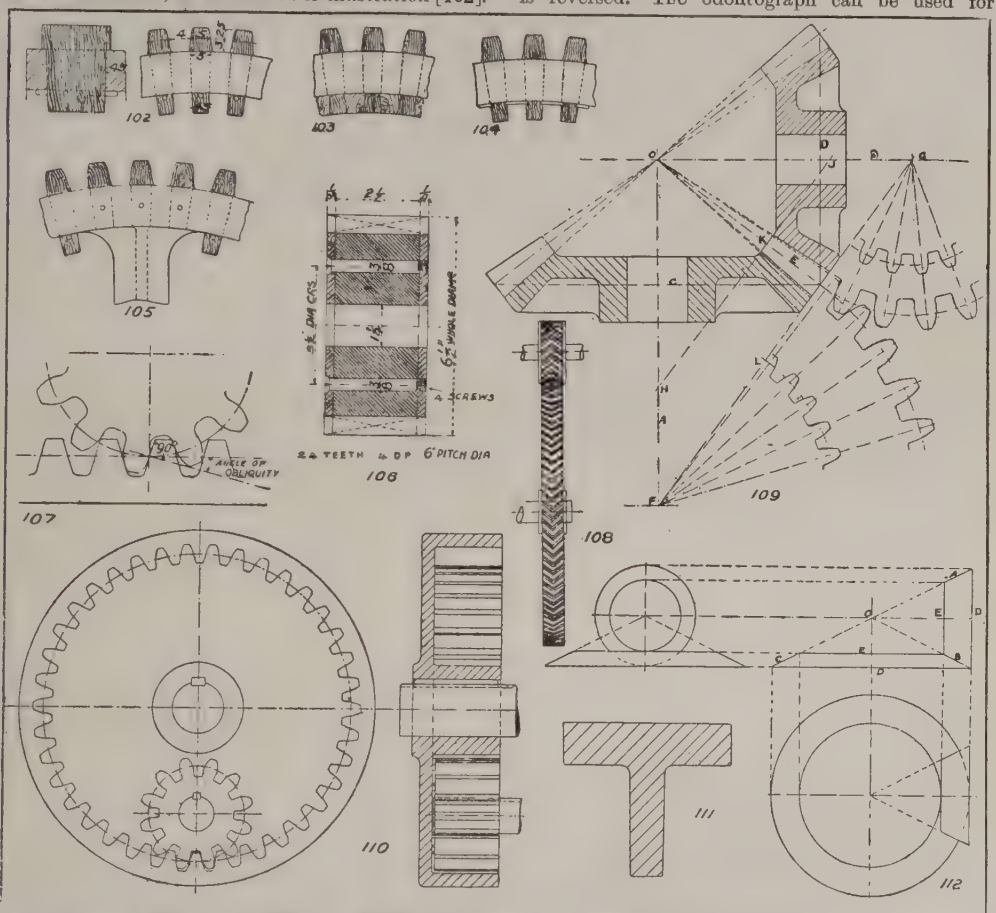
As in the case of rope wheels, there is a limiting speed beyond which gears should not be run. Cast-iron gears should not be run above 2000 ft. per minute at the pitch line; cast-steel gears, 2500 ft. per minute; small machine-cut gears, 3000 ft. per minute; above these speeds, gearing becomes noisy, and the wear is excessive.

Raw-hide Gears. Pinions which run at high speeds, such as those on electric motor spindles, are frequently made of raw hide. Discs of ox-hide are cemented together in layers under pressure in order to form the rough blank, which is then machined all over to finished sizes; side-plates—usually of gun-metal—are fitted as shown in section **106**, and the teeth are cut through the hide and through the metal plates. The object in using raw hide is to ensure noiseless running.

Mortise Teeth. Another and an older device to ensure a quiet running gear is to make the wheel teeth of wood; such teeth are termed *cogs;* are made separately by hand labour, and then fitted into slots cast in the wheel rim. Fig. **102** shows a good method of securing the teeth, as well as the proportions for tooth and wheel rim; the figures given are to be multiplied by the circular pitch in order to obtain the actual dimensions. Mortise wheels are used in flour-mills, cotton-mills, etc. The cogs are made of well-seasoned oak, acacia, hornbeam, or apple-tree, and the grain must run in a radial direction, as shown in the illustration [**102**].

necessary to make it right and left, or *double helical,* as it is termed, in order to avoid end-thrust on the shafts. These gears are frequently cast, but increasing numbers are being machine-cut. They are used for rolling-mill engines when reversal under load occurs. The usual angle for the teeth is 30 deg. measured from a horizontal line parallel with the shaft.

Internal Gears. These gears are made by forming the teeth upon the inside of the wheel rim, as indicated in **110**. The principle of tooth formation is the same as for outside teeth, but the spaces become the teeth —namely, the tooth curve is reversed. The odontograph can be used for



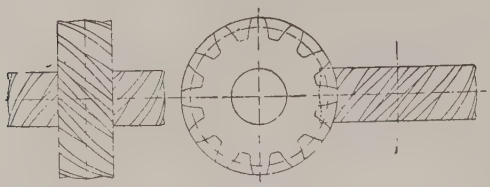
102–105. Mortise teeth (**102.** pinned; **103.** wedged; **104.** plated; **105.** pinned at arms); **106.** Raw-hide pinion; **107.** Rack and pinion; **108.** Helical toothed spur-gear; **109.** Bevel wheel and pinion; **110.** Internal spur-gear; **111.** Bevel wheel (arm section); **112.** Conical cylinders for bevels

Instead of holding the teeth by means of pins, wooden wedges, as **103**, or steel plates, as **107**, may be used: and pins are used where the arms occur, as in **105**. This class of gear is expensive, and is gradually falling into disfavour.

Helical Teeth. A quiet gear drive is obtained by making the teeth short lengths of a right and left hand screw or helix, as shown in **108**; the theory of construction is based upon an almost obsolete form of gear termed *stepped gear,* where the width of the teeth is divided into a number of equal parts, and each part is moved slightly in advance of its fellow. The merging of these steps into a straight line gives a helical curve to the tooth; it is

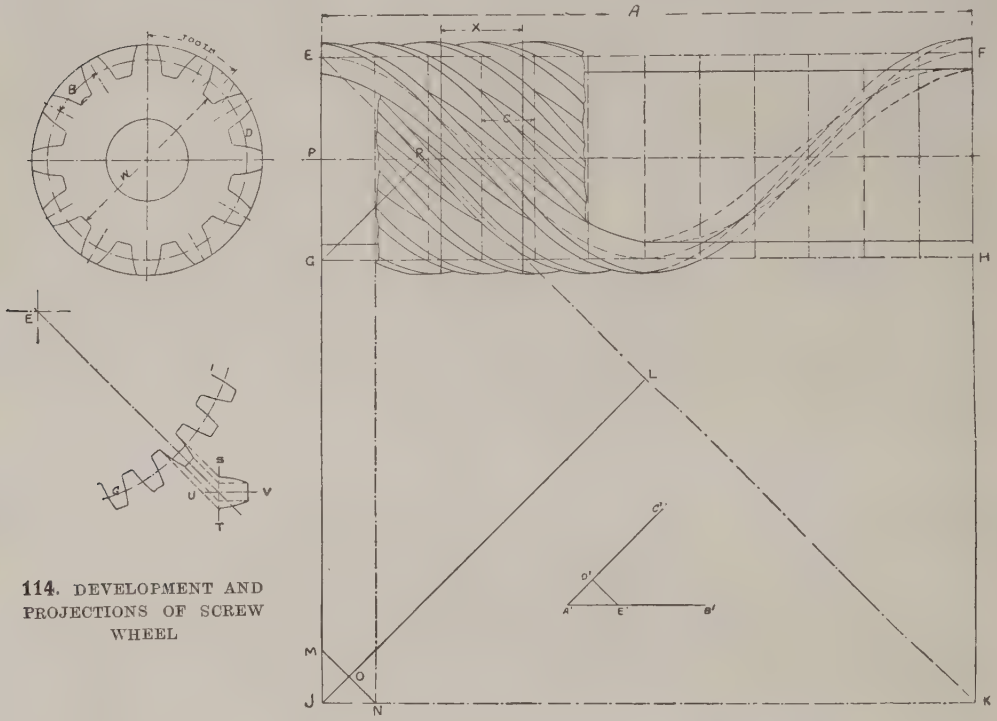
cycloidal teeth, but the face curve is marked from the flank data on the instrument, while the flank curve is marked from the face data. If involute teeth are struck, then the curve becomes concave instead of convex. When the ratio of wheel and pinion becomes very small, difficulties are encountered by reason of the teeth fouling each other. Normally, there should be at least a difference of 15 teeth between wheel and pinion. Internal gears are used on lathe headstocks, revolving gears on cranes, and so forth, or in cases in which both driving and driven shaft must rotate in the same direction.

Rack. A rack is a straight line of teeth, as **107**. It is used to produce rectilinear motion from



113. SCREW GEARS

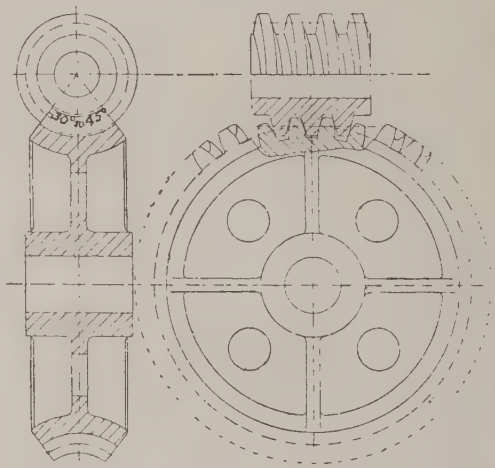
together, their axis being at right angles. The screw threads on both wheels are of the same hand; the number of teeth is counted as the number of screw threads involved, in the same way as we would speak of a double, triple, or quadruple thread screw. In the case illustrated there are 12 threads, or teeth, in each wheel; they will therefore transmit motion at equal velocities. But such gears can be made with different diameters and numbers of teeth, in order to give different velocities. The method of



114. DEVELOPMENT AND PROJECTIONS OF SCREW WHEEL

rotary motion, or vice versa; it is applied to tables of planing machines, the operation of sluice-doors, and so forth. The teeth may be marked out with the odontograph for cycloidal curves. If a rack is required to gear with an involute pinion, then the face and flank become a straight line drawn at right angles to the angle of obliquity, as in **107**. A rack is, in effect, part of a circle of infinite diameter; the circumference of a circle approaches a straight line as the diameter increases, and when the diameter is infinite any part of the circumference is a straight line. Cycloidal curves are formed by the rolling of generating circles upon a straight line, as well as upon a curved line, but an involute struck from a straight line is a straight line.

Screw Gears. When the axes of wheels gearing together are not in the same plane, recourse is had to *screw* or *spiral* gears. The teeth are formed upon cylindrical surfaces, but they are not parallel with the axes of the cylinders; each tooth is a portion of a spiral thread or helix. A screw wheel may have any number of such teeth from one upwards; a one-toothed screw wheel is termed a *worm*, and corresponds to a single-thread screw; a many-toothed wheel corresponds to a multiple-thread screw. The section of these screw threads is a standard tooth form, generally the involute. Fig. **113** shows a pair of screw wheels gearing

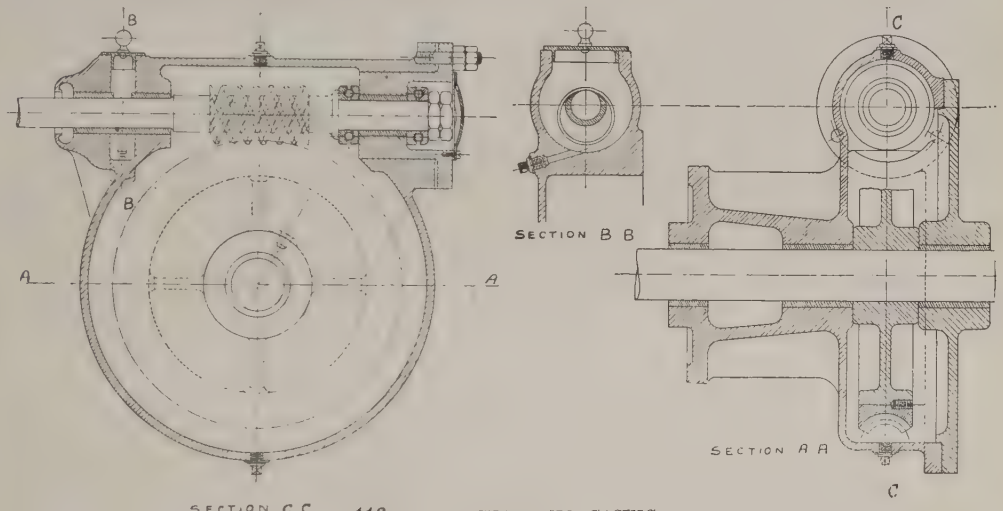


115. WORM AND WORM WHEEL

drawing a screw wheel is shown in **114**, together with explanatory projections. The *primary pitch* or *lead of spiral*, A, is the length of cylinder required to complete a turn of the screw or spiral; the *circular*

pitch, B, is the distance between the centres of adjacent teeth, measured around the circumference; the *normal pitch* is the distance between the centres of adjacent teeth, measured at right angles to the spiral; the *divided axial pitch*, C, is the distance between the centres of adjacent teeth measured on the axial line.

The normal pitch may be regarded as the true pitch of the teeth, as compared with the circular pitch of a spur wheel; for although it does not represent direct circumferential measurement, yet the standard tooth profiles and proportions are based thereon. Pitch diameters, spiral leads, and circular pitches may vary in any two wheels in gear, but the normal pitch must be constant, otherwise they will not work together. In order to set out a screw wheel, it is convenient to start with the circular pitch, and this is readily obtained from the normal pitch by means of the diagram in **114**. Draw a horizontal line, A′ B′, and extend a line, A′ C′, representing the tooth angle, and draw a line normal to this and of a length equal to the normal pitch, D′ E′; then A′ D′ equals the circular pitch. When the axes of the shafts intersect at right angles, as in **113**, it is essential that the sum of the respective tooth angles be 90 deg., and it is, of course, convenient to make each one 45 deg.



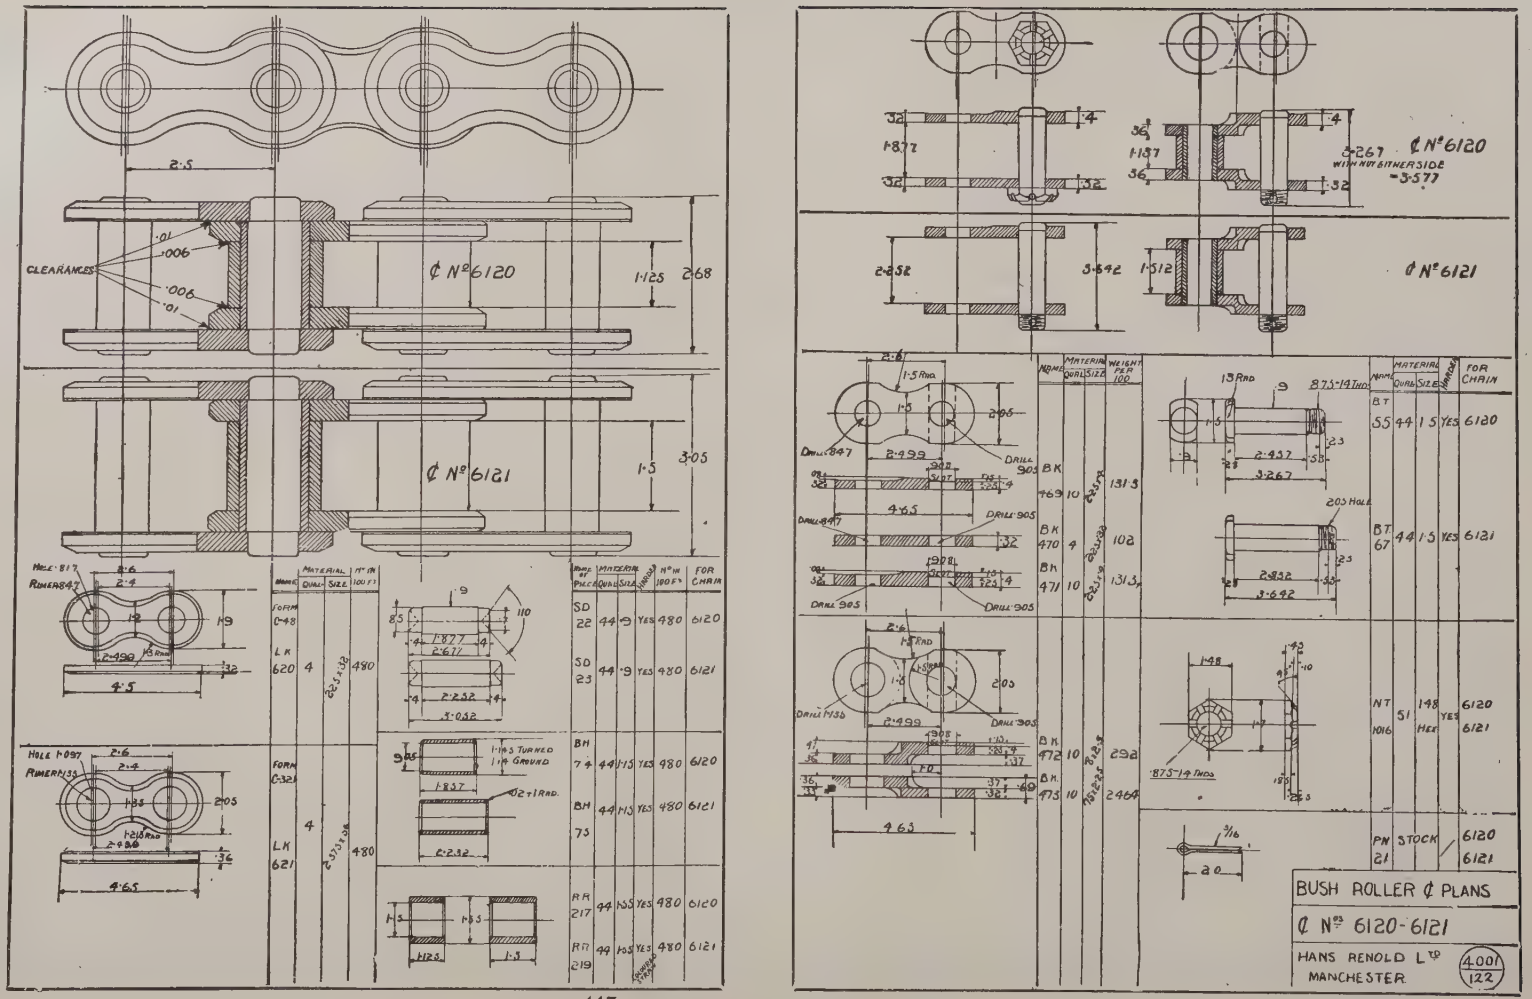
116. WORM GEAR AND CASING

Delineating the Spiral. Having obtained the circular pitch, calculate the pitch diameter, as in the case of spur gears, and draw the pitch circle, D, in face elevation [**114**], and also in side elevation, E F G H, which latter may be termed the *pitch cylinder*. Unroll this cylinder until the length, E J, represents its circumference, and then draw the diagonal, E K, which is the developed spiral, and lay down a line from J to L perpendicular to E K. Now divide E J into as many parts as there are teeth in the wheel. Taking one of these parts, J M, we have the circular pitch. Then divide J K into the same number of parts, and take one of them, J N; draw a line from N to M, cutting J L at O, and then J O is the normal pitch, and J N is the divided axial pitch. The next step is to develop the end elevation of the teeth in order to draw the face view. To do this it is first necessary to ascertain the diameter of the normal pitch circle, and this must be measured in the same plane as the normal pitch. Upon the line E J mark off a distance, E P, equal to the radius of the pitch cylinder, and draw a horizontal line, P R, cutting E K at R; then lay down a line, R G, perpendicular to E K, and E G is the radius of the normal pitch circle. To develop the teeth, transfer the radius, E G, to the lower left-hand view [**114**], and upon it mark out involute teeth of the pitch required, as in ordinary spur gears. Selecting a tooth whose centre line coincides with the angle of the spiral, we project its various thicknesses upon a vertical line, S T, and re-project them upon a horizontal line, U V, the depth of the tooth remaining the same in each case. We may now transfer the tooth developed on line U V to the face elevation of the wheel. The teeth and the spaces look abnormally wide, but this is, of course, due to the fact that they are not perpendicular to the face of the wheel.

The pitch line is now projected upon the cylinder in the same manner as we projected the helix and the screw head on page 5404. A tooth may be also projected in a similar way by considering it to be coiled on a cylinder of a diameter equal to that of the wheel measured under the teeth, as W. There is no necessity to draw the complete helix in actual practice, but it is shown so in **114**, in order to present the principle in as clear a manner as possible. Further teeth may be drawn without the labour of projecting each one. Make a tracing of one half helix, and move it successively one axial pitch, pricking off the tooth points in turn; the tooth curves may then be drawn through the points so obtained. A slice may be taken from the cylinder of projected spirals, as X, and this slice is the screw wheel required. The width, X, should be sufficient to ensure at least one pair of teeth being well in contact before the next pair leave contact. This is attained if the width be made to contain a pitch and a half measured circumferentially, as shown in the face elevation.

Screw gears may be made with their axes at various angles, and with wheels of various diameters; the teeth of helical gears, as mentioned earlier in this lesson, are portions of similar spirals.

The Worm and Wheel. This is a true screw gear, with axes usually, though not necessarily, at right angles [**115**]. The worm may be a single thread or multiple thread, the wheel containing many portions of internal threads, formed



117. BUSH ROLLER CHAIN DRAWING

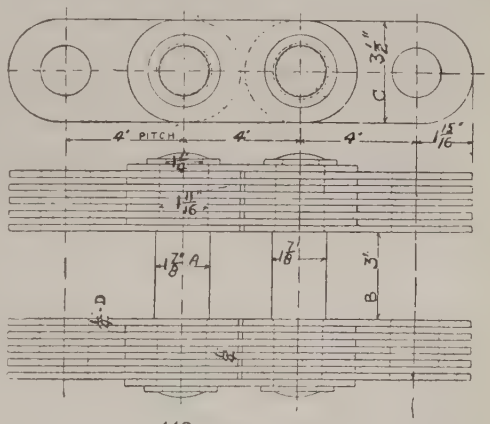
on an external surface. The sections of the threads are involute teeth, those of the worm having straight faces and flanks similar to a rack. The projection of the worm presents no difficulty, since it is a true spiral. The number of threads on the worm affects the speed of the worm wheel in direct ratio—that is to say, a single, double, or triple thread worm driving a wheel having, say, 33 teeth would have to make 33, 16½, and 11 revolutions respectively to each revolution of the wheel. Worm gears are generally used for the purpose of speed reduction on account of the great difference obtainable in a small space. Fig. **116** shows a typical example of a worm gear reduction in an oil-tight case. The worm wheel itself has a phosphor-bronze rim, in which the teeth are cut, this rim being fitted tightly on to a cast-iron centre, and secured thereon by means of four set-screws, spaced circumferentially. The worm is of mild steel, triple threaded, left hand; the wheel has 60 teeth. The worm shaft is coupled to an electric motor spindle running at 500 revolutions per minute, and the speed of the worm wheel shaft is therefore $\frac{500 \times 3}{60} = 25$ revolutions per minute. The casing is of cast iron, and has a circular bracket cast on as shown, in order to support it. This bracket may be arranged in any position desired to suit the application of the gear reduction—that is, it may be cast underneath or on one side if necessary. The casing forms an oil-bath for the gear to run in, and the worm should preferably be arranged underneath the wheel, so as to ensure plenty of oil getting at the working teeth. Ball bearings are fitted to the worm spindle to reduce the friction due to the end-thrust of the worm, these bearings being carried in a gland-shaped casting, which enables them to be removed bodily with the worm. It will be noticed that the worm is solid with the spindle, which is usual with small worms, as there would not be sufficient metal left under the threads if they were bored out for the reception of the spindle. A small oil-bath is also arranged for the worm spindle, and an oiling ring rests on the spindle and dips into the oil; this is the common device adopted to secure the proper lubrication of high-speed shafts in connection with motors and dynamos, and the like.

The diameter of a worm is generally from three to five times the circular pitch, and the angle of engagement, which determines the width of a worm wheel is usually 30° to 45°, as indicated in **115**.

Bevel Gears. We have hitherto only dealt with gears having their teeth formed upon parallel surfaces; bevel gears have their teeth formed upon conical surfaces, and are used for connecting shafts which are not parallel. Fig. **112** gives three views of a pair of conical cylinders in contact, having their axes at right angles and intersecting at O. Considering the lines of contact A, B, and C as pitch lines, ordinary cycloidal or involute teeth may be formed upon them; the pitch circle, the pitch, and the section of tooth are reduced from the "major" diameter, D, to the "minor" diameter, E, following radial lines to O. A section of a pair of bevels is given in **109**, together with the method of marking out the teeth at the major and minor diameters. Draw the axes or shaft centre lines, O A and O B, intersecting at O; then the major diameters, C and D; then the pitch lines extending to O; mark off the width of the tooth, E, and its depth and clearance; the major diameter is counted as the true pitch diameter, and the ordinary proportions of teeth, etc., apply there; the width of the tooth may be taken as the same as in spur gears. Lines are now drawn at right angles to the pitch lines of the teeth and extended to F and G and to H and J; arcs are then struck from F and G, the outer arc in each case being the developed pitch circle at the major diameter, and upon which the teeth are marked out as in spur gears, the inner arc being the developed pitch circle at the minor diameter. The radius of the inner arc for the bevel wheel is taken from H K, and is transferred to F L; radial lines are then drawn from the outer arc to centre, F, and upon these lines the pitch and the tooth section diminish regularly. The corresponding depth of tooth is taken by compasses from the minor diameter in the sectional view. The development of the teeth on the inner arc of the pinion is dealt with in the same manner as for the wheel.

When bevel gears are made with equal diameter wheels they are termed *mitre gears*, from the fact that the pitch lines make an angle of 45° with the axes of the shafts. Bevel gears may be made with axes at other than right angles; if the angle be greater than 90°, they are frequently termed *angle spur gears*.

The thickness of the rims of bevel gears is made about ·56 of the pitch at the major diameter, and

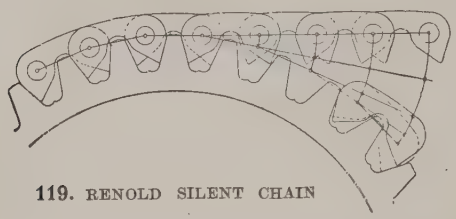


118. STUD CHAIN

decreases radially to the minor diameter. The arms are usually made T section, as in **111**, and to the proportions given for cross arms for spur wheels. The strength of a bevel tooth is calculated at the mean pitch. Bevel gears may be half shrouded or fully shrouded, and they may be made with helical teeth or with mortise teeth or of raw hide.

Gearing Chains. Gearing chains are used for transmitting power in cases where a flexible yet accurate drive is required. Their leading applications may be enumerated as follow: Driving steam-engine governors; driving line shafts from electric motors; driving motor-car axles; driving pumps and machine tools from electric motors; driving feed gears of machine tools; driving grain elevators and general conveyor work; travelling gear of steam and electric cranes; agricultural machinery, etc.; hoisting tackle for pulley-blocks and cranes. There are various types of gearing chains in use, and each type has its sphere of application more or less distinct from its fellows. The leading types are the *stud chain*, the *block chain*, the *bush roller chain*, and the *patent silent chain*.

The Stud Chain. Fig. **118** shows a heavy stud chain as used for hoisting tackle. It is designed for a working load of 10 tons, and a factor of safety of 10, consequently its breaking load would be 100 tons; a chain of this nature is designed simply for

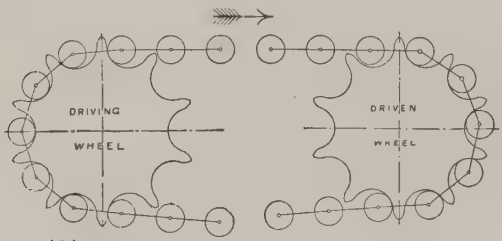


119. RENOLD SILENT CHAIN

strength, and has not sufficient wearing surface to render it suitable for transmitting power except at very slow speeds, not exceeding, say, 50 ft. per minute.

The Block Chain. This is suitable for speeds up to 500 ft. per minute. The block may be hollowed or flat; the design of this chain, as well as those which follow, is based upon the provision of ample wearing surface rather than upon actual strength; the proportions are settled by practice rather than by calculation. Accordingly, the selection of a chain for any particular duty is best left in the hands of expert manufacturers.

The Bush Roller Chain. Suitable for speeds up to 800 ft. per minute, the construction of this chain will be seen from **117**. The rivets of the chain carry hardened bushes, which form a

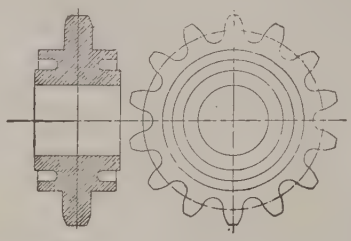


121. DIAGRAM OF CHAIN AND WHEELS

bearing for the anti-friction rollers which engage with the wheel teeth.

The Renold Silent Chain. With this chain 1250 ft. per minute can be attained [**119**]. The construction is unique, and the action of engaging with the wheel teeth is entirely different from ordinary chain gears. To understand this better, we will first investigate the action of ordinary chains and the formation of wheel teeth.

Fig. **120** illustrates a wheel suitable for working with the chain shown in **118**; the tooth curves are involute, and there is just enough space at the roots for the easy working of the studs as the chain enters and leaves the teeth. This is the simplest form, and works satisfactorily with slow speeds and uniform loads. As speeds increase and loads vary, this construction must be modified; the best-made chain will stretch, and then the wheel has to accommodate a varying and an increasing pitch. Another complication has also to be met: the driving wheel has a tendency to run faster than the chain, while the driven wheel tends to lag behind the chain; this effect is seen in **121**, which is slightly exaggerated in order to show the clearing allowances made. The pitch of the teeth is greater than the pitch of the chain in the case of the driving wheel, and the tooth spaces are much wider than actually required for the accommodation of the roller alone; by such construction the above-mentioned difficulties are overcome, but the life of the chain is seriously impaired if run beyond a speed of, say, 800 ft. per minute. The difference in pitch between the chain and the wheel gives rise to a series of little shocks as the load is transferred from tooth to tooth while running, such shocks being the cause of the wear and noise which considerably limit the speed.



120. STUD CHAIN WHEEL

Referring now to the patent silent chain [**119**], we see that the action of the links is to come quietly into position without slide or shock; when the teeth are worn, or when the chain is stretched, the chain rises automatically up the wheel tooth, as in **122**, and so accommodates itself to altered conditions, and maintains a silent drive. The chain consists of a number of links of the outline shown, there being from 4 to 12 abreast according to power transmitted. There are various modifications of construction adopted to suit different drives, but the above principles do not alter.

Chain Wheels. Chain wheels are ordinary castings for heavy stud chains, but are invariably machine-cut for all other types. The diameter of a wheel is naturally kept as small as possible, in order to keep the chain speed down, and also to save expense. When using *block chains*, the limit of teeth in the pinion may be taken as six, although smaller ones have been employed for special work. With *roller bush chains*, eight teeth are considered to be small enough for ordinary work, while the ratio of the wheel and pinion should not be more than 7 or 8 to 1. The smallest wheels for the patent silent chain should not contain less than 15 or 18 teeth, according to construction of chain; the *gear ratio* recommended should not be more than 5 to 1.

It is desirable to arrange a gear drive so that it contains an even number of links or pitches; when this is unattainable recourse is had to special links, as shown in the top right-hand corner of **117**, where they are cranked to fit outside of the links they would come abreast of.

Chain Belting. A chain belt is a form of metallic chain used largely for elevating and conveying machinery; the links are usually of malleable cast iron. The design and manufacture of this chain is even more in the hands of specialists than that of the foregoing type; consequently, the draughtsman is rarely called upon to design chain belting.

122.
RENOLD SILENT CHAIN WHEN WORN

Friction Wheels and Clutches. These are used for the transmission of power, at intermittent intervals, from constantly moving machinery; or for rapidly disconnecting a portion of moving mechanism; or for connecting machinery to an engine after it has been started up. A common application of

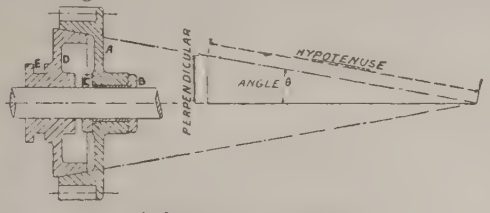
the latter form is met with on motor-car work, where the engine is not capable of starting up against full load.

The principles underlying this class of mechanism are discussed on page 1303, and applications are illustrated on pages 1305 and 1308 in MECHANICAL ENGINEERING. We therefore proceed to delineate more fully several leading types.

Fig. 123 shows a flat-faced friction wheel and pinion as used on a friction hoist. The wheel is keyed to the rope-barrel of the hoist, and the barrel runs loose upon the shaft. The end of the shaft is formed eccentrically, and is moved through a portion of an arc by means of the lever and cord. This movement brings the friction wheel into contact with its pinion, which latter is running constantly; the friction set up between the two surfaces causes the wheel to revolve. The barrel, being keyed to the wheel, must go with it, and so the load is lifted. The calculations involved are simple, and may be stated thus: The load to be lifted is 1 ton; the corresponding load on the periphery of the wheel is

$$\frac{\text{load} \times \text{A}}{\text{B}} = \frac{2240 \times 9}{15} = 395 \text{ lb.}$$

Assuming the coefficient of friction to be ·2 (cast



124. FRICTION CONES

iron on cast iron), then the pressure required between the wheel and pinion is

$$\frac{395}{\cdot 2} = 1975 \text{ lb.},$$

and the load on the operating cord is therefore

$$\frac{1975 \times \text{C}}{\text{D}} = \frac{1975 \times \cdot 75}{70} = 21 \text{ lb.}$$

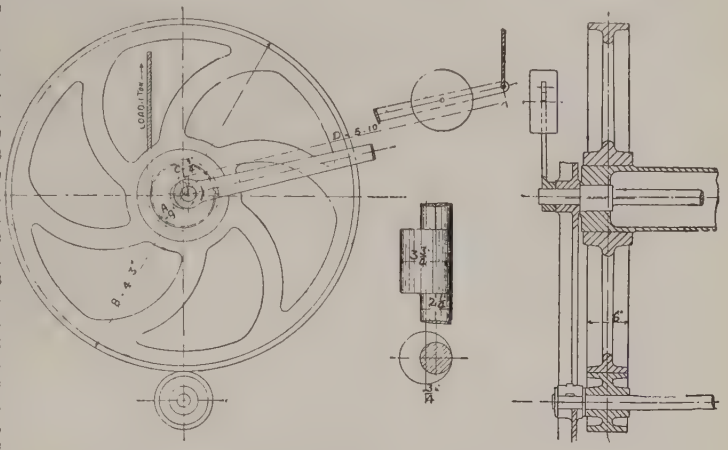
which is quite within the capacity of an average man to manipulate. The pulleys are designed as ordinary belt pulleys, but are somewhat heavier throughout, to withstand shocks due to the sudden application of the load. An enlarged view of the eccentric formation of the shaft is given in 123, which illustrates a neat way of making a very short lever arm.

The weight near the end of the long lever is so placed in order to ensure the large pulley returning to contact with a brake block arranged overhead when the hand cord is released. The width of the wheel is 6 in. in the case illustrated, and this works out to

$$\frac{1957}{6} = 329 \text{ lb. per inch of width.}$$

This represents average practice. High pressures per inch of width tend to heat the pulleys.

Friction Cones. Friction cones or *cone-couplings* are used for coupling shafts while one of the shafts is running, or for taking power from a revolving shaft. The latter application is shown in 124, the view illustrated being a section, and all portions circular. The outer cone piece, A, is bushed and runs

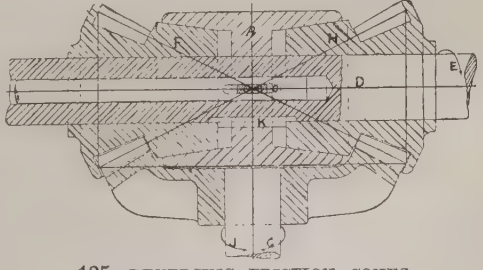


123. FRICTION WHEELS

loose on the shaft, being kept in its place endwise by means of the collars, B and C. Teeth are cast on the outside periphery, which engage with corresponding teeth of a spur wheel. The inner cone piece, D, slides upon feathers fitted in the shaft, and is moved by suitable lever gear fitted to the groove, E. Driving of the spur gear takes place when the cones are pressed together with sufficient force to overcome the resistance to slipping between their surfaces. The end pressure required depends upon the coefficient of friction and upon the angle of the cone. The general formula in use is

$$\text{P} = \frac{\text{L} \times \text{sine } \theta}{\mu},$$

where P is the necessary end pressure. L is the load to be transmitted at the mean diameter of the cone. θ is used to denote the angle; "sine" is the trigonometrical ratio of the angle θ, and is found by dividing the perpendicular by the hypotenuse; μ denotes coefficient of friction. The

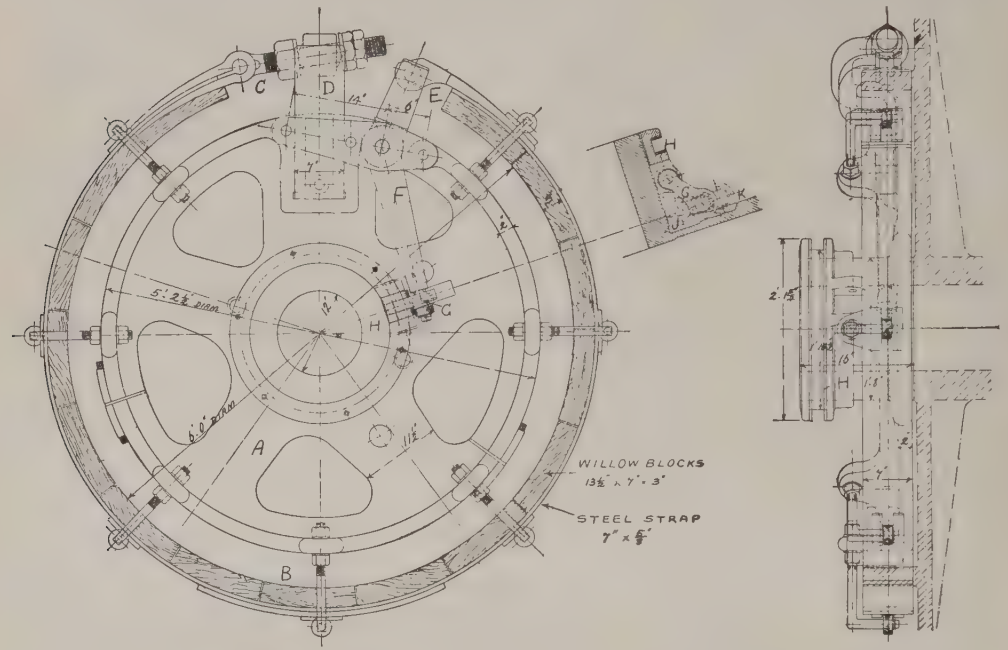


125. REVERSING FRICTION CONES

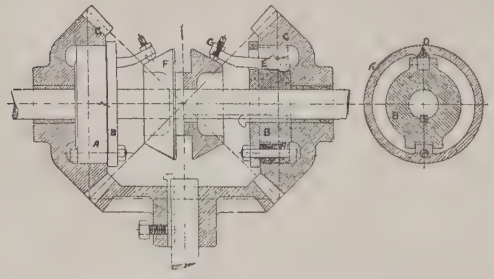
angle θ is usually 10 deg., and μ may be taken as ·2 for cast iron on cast iron.

Reversing Cones. Another application of the foregoing type of cones is shown in 125. The outer cone, A, is in this case driven from the shaft by means of the cottar, B, which passes through a slot, C, in the shaft. This cottar also passes through a central rod which is moved endwise at the centre of the shaft. The outer cone is double-ended, in

order to engage with either the right or left hand inner cones, and these latter are each cast in one piece with a bevel pinion, and both pinions gear into a single bevel wheel; the shaft, D, runs continuously, and carries the outer cone with it. When the shaft is running in the direction of the arrow, E, and the cone, F, is engaged, then the bevel wheel runs in the direction of the arrow, G; but if the cone, H, be engaged, then the bevel wheel revolves in the direction of arrow, J. The central rod device can only be used when the cones are located a short distance from the end of the shaft. Failing this, they may be moved, as in the case of **124**, by forming the groove around the centre of the outer cone. The feather, K, assists to drive the outer cone, and its ends keep the inner cones at their proper distance apart. Sometimes collars are fitted at the ends of the feather in order to prevent the ends of the cones from being cut by the feather.



126. THE "WELLMAN SEAVER MORGAN" CLUTCH



127. EXPANDING RING CLUTCH

Friction Clutches. The principal objection to the use of the friction devices just described is the resulting end pressure upon the bearings of the shafting. Figs. **126** and **127** show two friction clutches which are practically free from this defect.

An *expanding ring clutch* is seen in **127**. It is double-ended or reversible. The expanding ring, A, is driven from the shaft by key and by the piece, B. It is expanded to drive the hollow of the mitre wheel, C. In order to effect the expansion, the ring is divided at D, and receives a steel wedge piece, which is forced up by another wedge formed on the lever, E. This lever is moved by striking the cone piece, F, to the right or to the left. The angles of the wedges and of the cone are such that they slip back when the pressure is removed. The adjusting screw, G, on the end of the lever provides means for following up the wear on the working parts, and so keeping the relative stroke of the cone a constant.

A friction clutch which has wide applications amongst mill work and winding engines, and can be built to transmit thousands of horse-power, is shown in **126**. It is made by the Wellman Seaver Morgan Co., Ltd. It consists of a centre driving disc, A, which is keyed to the shaft, and carries with it a wood-lined strap, B, which is adjustable by means of its anchored end, C, on a driving piece, D, and is tightened by the end marked E and the lever, F, the tail end of which has a spherical connection with the link, G. The sliding collar, H, is moved by suitable striking levers, and causes the link, G, to move the ball end of the lever, F, from position J to position K. The strap is thus tightened upon the rim of any drum or wheel which may be interposed between the strap and the driving disc, A, as shown in chain-dotted section. Such interposing rim does not have any contact with disc A.

The leading dimensions of one of these clutches are given on the drawing [**126**], which is 6-ft. diameter, and can transmit 11-horse power per revolution, with a maximum load of 20,000 lb. on the rim.

Use of Subjunctive. Sequence of Tenses. Agreement of Past Participle. Remarks on Adverbs, Prepositions, and Conjunctions.

FRENCH

Continued from page 5534

By Louis A. Barbé, B.A.

VERBS

Use of the Subjunctive—continued

5. The verb must be in the subjunctive when it is preceded by a relative pronoun having for its antecedent a noun qualified by a superlative, or by some word equivalent to a superlative, such as: *le premier*, the first; *le dernier*, the last; *le seul*, the only: *Le chien est le seul animal dont la fidélité soit à l'épreuve*, The dog is the only animal whose fidelity can be relied on (lit. is proof).

When the superlative is followed by an indirect object the verb is in the indicative: *Le soleil est le plus grand des corps que l'on aperçoit dans le ciel*, The sun is the largest of the bodies that we perceive in the heavens.

6. After *quel que* (*quelle que, quels que, quelles que*), whatever; *qui que*, whosoever; *quoi que*, whatsoever, the subjunctive is required in the subordinate clause: *Quel que soit le mérite d'un homme, il ne peut échapper à l'envie*, Whatever a man's merit may be, he cannot escape envy.

7. *Quelque . . . que*, and *si . . . que*, meaning whatever, however, require the verb following them to be in the subjunctive: *Quelque effort que fassent les hommes, leur néant paraît partout*, Whatever effort men may make, their nothingness is everywhere apparent.

8. When *que* is used to avoid the repetition of *si*, the verb that follows it must be in the subjunctive: *Si vous passez par cette ville et que vous puissiez disposer d'une couple de jours, ne manquez pas de vous y arrêter*, If you pass through that town, and if you can spare a couple of days, do not fail to make a stay there.

9. The subjunctive is used (*a*) after conjunctions indicating time before which, or time up to which, as *avant que, en attendant que, jusqu'à ce que*; (*b*) after conjunctions indicating purpose or result, as *afin que, pour que, de crainte que, de peur que*; (*c*) after conjunctions implying a condition or supposition, as *en cas que, au cas que, à moins que . . . ne, pourvu que, supposé que*; (*d*) after conjunctions implying a concession, as *quoique, bien que, encore que, soit que . . . soit que; soit que . . . ou que; pour peu que, si tant est que*; and (*e*) after conjunctions involving a negation, as *non que, non pas que, loin que, sans que*:

(*a*) *Je lui ai payé cette somme avant qu'il partît*, I paid him that amount before he left.

(*b*) *Ce livre est toujours sur le bureau, afin qu'on puisse le consulter*, That book is always on the desk, so that it may be consulted.

(*c*) *Pourvu qu'on sache la passion dominante de quelqu'un, on est assuré de lui plaire*, Providing we know the master-passion of any one, we are sure to please him.

(*d*) *Quoiqu'il soit pauvre, il est un honnête homme*, Although he is poor, he is an honest man.

(*e*) *Je dis cela, non que je veuille me plaindre, mais pour que vous sachiez ce qui s'est passé*, I say this, not that I wish to complain, but that you may know what has taken place.

10. The subjunctive occurs in elliptical sentences expressing a wish or a command; and, in such cases, the conjunction *que* is sometimes omitted: *Que Dieu vous ait en sa sainte garde*, May God have you in His holy keeping; *Vive le Roi!* Long live the King!

11. The subjunctive is used idiomatically in the expression *je ne sache*, followed by a negation, and *que je sache*, preceded by one: *Je ne sache rien qui soit plus digne de notre amour que la vertu*, I know of nothing that is more worthy of our love than virtue; *Cette affaire ne le regarde nullement, que je sache*, This matter does not concern him in any way that I know of.

Sequence of Tenses. 1. When the verb of the governing clause is in the present, whether indicative, subjunctive, or imperative, or in either of the future tenses of the indicative, the verb of the subordinate clause must be in the present subjunctive if it be intended to express an action or a state considered as either present or future in respect of the governing verb: *Il faut que je sorte maintenant*, I must go out now.

2. When the verb of the governing clause is in the present, whether indicative, subjunctive, or imperative, or in the future indicative, the verb of the surbordinate clause must be in the perfect subjunctive if it be intended to express an action, or a state considered as past in respect of the governing verb: *Je ne crois pas que vous ayez fait tous vos efforts*, I do not think you have done your utmost.

3. When the verb of the governing clause is in any past tense of the indicative or subjunctive, or in either tense of the conditional, the verb of the subordinate clause must be in the imperfect subjunctive if it be intended to express an action or a state considered as either present or future in respect of the governing verb: *Je voulais qu'on retardât le départ*, I wished the departure to be delayed.

4. When the verb of the governing clause is in any past tense of the indicative or of the subjunctive, or in either tense of the conditional, the verb of the subordinate clause must be in the pluperfect subjunctive if it be intended to express an action or a state considered as past in respect of the governing verb: *Je ne savais pas que vous m'eussiez écrit*, I did not know that you had written to me.

5. When the verb of the governing clause is in the past indefinite, the verb of the subordinate clause is frequently put in the past subjunctive instead of the pluperfect subjunctive: *Il a fallu qu'il se soit donné bien des peines*, He must have given himself a great deal of trouble.

6. A past indefinite in the governing clause may be followed by a present subjunctive in the subordinate clause to express an action or a state which is still present: *Cet auteur n'a employé aucune fiction qui ne soit une image de la vérité*, That author has used no fiction that is not an image of truth.

Agreement of the Past Participle

1. The past participle, when not accompanying an auxiliary verb, is practically an adjective, and agrees in gender and number with the noun or pronoun to which it refers: *Voyez-vous là-bas ces collines couronnées de bois sombres?* Do you see yonder those hills crowned with dark woods?

Exception: A certain number of past participles really become prepositions when they precede a substantive, and are then invariable. The chief of them are: *attendu*, considering; *vu*, seeing; *excepté*, except; *y compris*, including; *ci-inclus*, enclosed: *Excepté vous et moi*, Except you and me.

These participles agree in the ordinary way when they come after the noun or pronoun to which they refer: *Vous et moi exceptés*, You and I excepted.

2. When the past participle is accompanied by the verb *être*, to be, as is the case in all the tenses of passive verbs and in the compound tenses of some neuter or intransitive verbs, it always agrees in gender and number with the subject of the verb: *La vertu obscure est souvent méprisée*, Obscure virtue is often despised.

3. When the past participle is used in connection with *avoir*, to have, to form the compound tenses of an active verb, it agrees in gender and number with the direct object of the verb, providing that direct object precedes the verb: *J'ai reçu toutes les lettres que vous m'avez adressées*, I have received all the letters which you have addressed to me.

In this example *reçu* does not agree with the direct object, because that object—*i.e.*, *toutes les lettres*—comes after it. *Adressées*, on the other hand, agrees with its direct object *que*, because that direct object precedes it.

4. It follows from this rule that, as a neuter verb cannot have a direct object, its participle is always invariable: *La justice et la modération de nos ennemis nous ont plus nui que leur valeur*, The justice and moderation of our enemies have done us more harm than their valour. In this example, the neuter verb *nuire* (= to injure, to do harm) governs *nous* in the dative, or indirect object. There can, consequently, be no agreement.

5. Pronominal, or reflexive, verbs are conjugated in their compound tenses with the help of *être*, to be. This auxiliary, however, is equivalent to *avoir*, to have; and the rule for the agreement of the past participle is the same as in the case of the past participle conjugated with *avoir* [see above, 3]: *Ces hommes se sont repentis*, Those men have repented. In this sentence *se* is the direct object of the pronominal verb *se repentir*, to repent; and consequently the past participle agrees with it.

Elle s'est plu à me contredire, She delighted in contradicting me. In this example, the pronominal verb *se plaire*, to delight in, is made from the intransitive verb *plaire*. The pronoun s' (= *se*) is governed by it in the dative. Consequently there is no agreement.

Nous nous sommes lavé les mains, We have washed our hands. Here the direct object of the pronominal verb *se laver* is the noun *mains*; and, as it does not precede the verb there is no agreement. On the other hand, the past participle agrees with the second *nous* in the following example, where it is the direct object: *Nous nous sommes lavés*, We have washed (ourselves).

6. The past participle of an impersonal verb, or of a verb used impersonally, can never have a direct object with which to agree: *Les chaleurs qu'il a fait pendant l'été*, The heat which was experienced during the summer. Here *il a fait* (= it has made) is used impersonally and idiomatically to indicate existence (= there has been).

7. The past participle *été* never changes under any circumstances: *La maison a été brulée*, The house was burnt. *Nous sommes ce que nous avons toujours été*, We are what we always have been.

Special Cases. 1. When the past participle conjugated with the auxiliary *avoir* and preceded by a direct object is followed by an infinitive, that past participle agrees with the object if it is the governing verb. It does not agree if the infinitive is the governing verb: *Les dames que nous avons entendues chanter*, The ladies whom we heard sing (singing). Here, the past participle agrees because it belongs to the verb governing *que*, whom. It is to be noted that in this case, the French infinitive *chanter* may be translated by the English present participle *singing*.

Les airs que nous avons entendu chanter, The melodies which we heard sung. Here the past participle does not agree, because not it, but *chanter* is the verb governing *que*. It is to be noted that in this case the French infinitive is translated by the English past participle *sung*.

The past participle *fait* does not come under this rule. When immediately followed by an infinitive it always remains unchanged (*fait*): *Une femme s'est présentée à la porte; je l'ai fait passer*, A woman presented herself at the door; I made her pass in.

2. It frequently happens that a governing infinitive is understood after the past participles of *devoir*, *vouloir* and *pouvoir*—*i.e.*, *dû*, *voulu*, *pu*. In that case the past participle does not agree with the preceding object: *Je lui ai rendu tous les services que j'ai pu*, I have rendered all the services which I could (*i.e.*, render him).

3. A past participle preceded by the relative pronoun *que*, and followed by the conjunction *que*, never agrees with the relative: *Les lettres que j'ai prévu que vous recevriez*, The letters which I foresaw you would receive.

4. The past participle does not agree with *en*, some, any: *Il a acheté plus de livres qu'il n'en a lu*, He has bought more books than he has read.

The past participle preceded by *en* may, however, agree with some other word also preceding it: *J'ai reconnu la maison d'après la description que vous m'en avez faite*, I recognised the house from the description you gave me of it.

5. After *le peu* the past participle remains unchanged if *le peu* is equivalent to "the want of": *Le peu d'affection que vous lui avez témoigné l'a découragé*, The little affection you showed him discouraged him.

If, on the contrary, *le peu* represents a positive quantity, a certain amount, the past participle agrees with the complement of *le peu*—*i.e.*, the noun coming after it: *Le peu d'affection que vous lui avez témoignée l'a encouragé*, The little affection you showed him encouraged him.

ADVERBS

Negation. 1. Negation is usually expressed by *ne* and *pas*, or *point* (which is rather stronger than *pas*). *Ce n'est pas moi qui vous l'ai dit*, It is not I who told you.

2. The second part of the negation is omitted after *savoir*, used with the meaning of *pouvoir*, to be able: *Je ne saurais en venir à bout*, I cannot manage it. In this construction the present conditional of *savoir* is used instead of the present indicative of *pouvoir*.

3. When *savoir* has its ordinary meaning of "to know" it requires *pas* when used negatively: *Il ne sait pas le français*, He does not know French.

4. When a verb used negatively is followed by a negative relative clause, that relative clause takes *ne* only: *Il n'y a personne qui ne le respecte,* There is no one but respects him.

5. When the negation is expressed by any word but "not," such as "never," "nobody," "nothing," etc., *ne* is used, but *pas* must be omitted: *Je ne dois rien,* I owe nothing.

6. In negations the order of the words is usually: first, *ne;* second, verb; third, second part of the negative expression. But when "nobody" or "nothing" is the subject of the sentence, *personne,* or *rien,* must precede *ne*: *Personne n'a voulu lui parler,* Nobody would speak to him.

7. "Neither—nor" must be expressed by *ne—ni*: *Elle n'a ni frère ni sœur,* She has neither brother nor sister.

8. Several negative expressions may occur in the same sentence, in which case *ne* is used only once: *Personne ne m'a jamais rien dit,* Nobody has ever said anything to me.

9. *Ne* is used alone and without any negative meaning: (*a*) After verbs and other expressions indicating fear: *Je crains que vous ne perdiez votre argent,* I fear you will lose your money. (*b*) After *que,* "than," in comparisons of superiority or inferiority having a verb for their second term: *Vous écrivez mieux que vous ne parlez,* You write better than you speak. (*c*) After *à moins que,* "unless": *J'irai me promener, à moins qu'il ne fasse mauvais temps,* I shall go for a walk unless it is bad weather.

Special Remarks. 1. *Auparavant* and *avant* both mean "before" (of time); but *auparavant* being an adverb has no complement, whilst *avant,* which is a preposition, requires one: *Nous lui avions déjà écrit quelques mois auparavant,* We had already written to him a few months before; *Je le verrai avant vous,* I shall see him before you.

2. *Davantage* and *plus* both mean "more," but *davantage* must not be followed by *que* nor by *de.* It therefore stands only at the end of a sentence: *Vous avez de l'argent, mais il en a davantage,* You have money, but he has more.

3. *Dessus,* "on, over"; *dessous,* "under, underneath"; *dedans,* "within, in"; *dehors,* "without, out," which are adverbs and take no complement, are to be carefully distinguished from the corresponding prepositions *sur, sous, dans, hors,* which require complements. These adverbs are frequently used instead of a preposition and a pronoun referring to an inanimate object: *Nous ouvrîmes la boîte, mais il n'y avait rien dedans,* We opened the box, but there was nothing in it.

4. *Plus tôt* and *plutôt* both mean "sooner," but *plus tôt* refers to priority of time, whilst *plutôt* indicates preference: *Il est revenu plus tôt que je ne croyais,* He has come back sooner than I thought; *Donnez-nous la mort plutôt que l'esclavage,* Give us death rather than slavery.

5. *Au moins* and *du moins* both mean "at least," but *au moins* indicates a minimum, whilst *du moins* corrects or limits a former statement: *Ce voyage vous coûtera au moins mille francs, du moins c'est ce qu'il m'a coûté l'année dernière,* That journey will cost you at least forty pounds—at least, that is what it cost me last year.

PREPOSITIONS

1. Prepositions, with the single exception of *en,* require verbs that follow them to be in the infinitive. After *en* the verb must be in the present participle: *En voyant son père il se mit à pleurer,* On seeing his father he began weeping.

2. The prepositions *à, de,* and *en* must be repeated before each complement: *Il dut la vie à la clémence et à la magnanimité du vainqueur,* He owed his life to the clemency and the magnanimity of the victor.

3. Other prepositions are usually repeated when the complements are opposed to each other in meaning: *Dans la ville et dans la campagne,* in town and country.

4. The prepositions *jusque,* as far as; *attenant,* adjoining; *par rapport,* with regard to; *quant,* as to, require the preposition *à* after them: *Il nous a accompagnés jusqu' à Londres,* He accompanied us as far as London.

But when *jusque* is construed with *où, ici, là, dans,* and *chez* it does not take *à* as well: *Il nous a accompagnés jusque chez nous,* He accompanied us as far as our house.

5. The preposition *de* is required after *auprès,* near; *autour,* around; *loin,* far; *près,* near; and *proche,* close, as well as after prepositional phrases, including a noun, as *à force,* by dint: *Ils demeurent près de l'église,* They live near the church.

6. *Avant* (before) requires no preposition before a noun or pronoun, but takes *de* before a verb: *Viendrez-vous nous voir avant de partir?* Will you come and see us before leaving?

7. When helping to form compound words, the preposition *à* conveys the idea of fitness, agency, peculiarity: *Un bateau à vapeur,* a steamboat.

8. The preposition *de* is joined to a noun of material to form a qualifying phrase: *Un chapeau de paille,* a straw hat.

9. The preposition *de* is used after *plus* and *moins* to express "than" before a numeral: *Vous avez plus de dix fautes,* You have more than ten mistakes.

10. The preposition *de* is used before *plus* and *moins* to express "more" and "less," when those words follow a numeral with a noun expressed or understood: *Vous avez douze fautes; il en a deux de moins,* You have twelve mistakes; he has two less.

11. The preposition *de* is used for "by" in expressions indicating excess or difference: *Vous le dépassez de toute la tête,* You are taller than he (exceed him) by a whole head.

12. The preposition *de* is used for "with" after verbs and adjectives expressing plenty, want, providing, depriving, etc.: *Il s'était rempli les poches de petits cailloux,* He had filled his pocket with little pebbles.

13. When a cardinal number is preceded by *en,* the adjective or past participle that follows that numeral usually takes *de*: *Sur cent habitants, il y en a deux de riches,* Out of a hundred inhabitants there are two rich.

14. When the verb "to be" has an infinitive coming after it for its logical subject that infinitive takes *de* or *que de* before it: *C'est mal de* (or *que de*) *parler comme cela,* It is wrong to speak so.

15. An infinitive following "than" takes *de* before it: *Il mourrait plutôt que de trahir sa patrie.* He would die rather than betray his country.

16. When a noun or an adjective used substantively serves as an epithet to qualify another noun, *de,* meaning "of a," is put before the qualified noun: *Un drôle d'individu,* a queer fellow.

17. The essential difference between *en* and *dans* is that *en* is only exceptionally used with the definite article *le, la, les,* whilst *dans* always requires it. Consequently nouns following *en* have usually an indeterminate meaning: *On l'a mené en prison,* He has been taken to prison; *On lui a permis*

d'entrer dans la prison, He was allowed to enter the prison.

18. *En* frequently means "in the character of," "like": *Vous parlez en soldat; je dois agir en roi,* You speak as a soldier; I must act as a king.

19. In expressions of time there is a great difference between *en* and *dans*. *En* indicates "time, how long," whilst *dans* indicates "point of time when": *Je ferai cet ouvrage en deux jours,* I shall take two days to do that work; *Je ferai ce travail dans deux jours,* I shall begin doing that work two days from now.

20. *En* is used in connection with all the seasons except spring, which takes *au*: *Il fait moins chaud au printemps qu' en été,* It is less warm in spring than in summer.

21. *À travers* and *au travers* both mean "through," but *à travers* means "through" in the sense of "across"; whilst *au travers,* which is always followed by *de,* rather means "right through," and implies a greater effort: *Nous courûmes à travers les champs,* We ran through the fields; *Il se fraya un passage au travers de la haie,* He forced his way through the hedge.

22. *Vers* and *envers* both mean "towards"; but *vers* refers to direction, whilst *envers* is used figuratively, in connection with feeling, sentiment, etc.: *Le premier moment de la vie est le premier pas vers la mort,* The first moment of life is the first step towards death; *Il s'est montré ingrat envers ses bienfaiteurs,* He showed himself ungrateful towards his benefactors.

CONJUNCTIONS

1. The conjunction *ni,* "neither," may be either used or omitted before the first of several subjects: *Le soleil ni la mort ne se peuvent regarder fixement,* Neither the sun nor death can be steadfastly gazed at; *Ni l'or ni la grandeur ne nous rendent heureux,* Neither gold nor greatness makes us happy.

2. The conjunction *ni* may be used to avoid the repetition of *sans,* "without"; *Sans crainte ni pudeur,* or *sans crainte et sans pudeur,* without fear or shame.

3. The English expressions "nor . . . either" "not . . . either," are to be translated by *ni . . . non plus, ne . . . pas non plus*: *Je ne le connais pas, ni elle non plus,* I do not know him nor her either; *Je ne lui écris pas, et il ne m'écrit pas non plus,* I do not write to him, and he does not write to me either.

4. The expression "either . . . or" may be expressed either by using *ou* before each term, or omitting it before the first: *Le ciel n'est ouvert ou qu'aux innocents ou qu'aux pénitents,* Heaven is open either to the innocent only, or the penitent only; *Le bonheur ou la témérité ont pu faire des héros,* Either good fortune or rashness may have produced heroes.

5. *Soit* and *soit que* both mean "whether," but *soit* precedes a noun, whilst *soit que* is followed by a verb. Both of them may be repeated before each term, or replaced by *ou* or *ou que* before the second: *La fortune, soit bonne ou mauvaise, soit passagère ou constante, ne peut rien sur l'âme du sage,* Fortune, whether good or bad, whether fleeting or constant, has no power on the soul of the wise man.

6. The conjunction *que* may be used to prevent the repetition of either *comme,* as: *quand,* when; or *si,* if. When replacing the last of these, it requires the verb that follows it to be in the subjunctive: *Comme nous l'avons déjà dit et que nous le verrons plus clairement ailleurs,* As we have already said, and as we shall see more clearly elsewhere; *Quand on est jeune et qu'on se porte bien on devrait aimer les exercices du corps,* When we are young, and are in good health we ought to like bodily exercise; *Si vous le rencontrez et que vous lui parliez, faites-lui mes amitiés,* If you meet him and speak to him, give him my kind regards.

7. *Que* may be used instead of *afin que,* in order that; *sans que,* but that; *lorsque,* when; *depuis que,* since; *de peur que,* lest; and *avant que,* until: *Approchez que je vous parle,* Draw near, that I may speak to you; *Je n'irai pas me coucher que ma besogne ne soit finie,* I shall not go to bed until my task is ready.

8. When, however, *que* takes the place of a conjunction which does not itself require the subjunctive (except the conjunction *si*), it is not followed by the subjunctive: *Je le ferai quand je serai revenu, et que j'aurai le temps,* I shall do it when I have returned and have the time.

BONNES RÉSOLUTIONS

Si je me lève tard et que je traîne tout le jour, je commencerai à peine mon ouvrage à la nuit; mais je me coucherai tôt, je me lèverai tôt, et j'obtiendrai par ce moyen, santé, richesse et sagesse. Je m'efforcerai d'être laborieux, afin que je n'aie jamais à craindre la disette (want). Il n'est pas nécessaire que je trouve un trésor, ni qu'il m'arrive un riche héritage; mon activité me suffira. Je travaillerai dès aujourd'hui, car je ne sais pas si je n'en serai pas empêché demain. Je rougirai de ne rien faire, alors que j'ai tant à faire pour moi-même, pour ma famille, pour mon pays. Je prendrai mes outils sans mitaines et je me souviendrai que chat ganté ne prend pas de souris. Peut-être me sentirai-je parfois le bras trop faible; mais je tiendrai ferme et je triompherai de tous les obstacles. J'emploierai bien mon temps, parce que je veux gagner du loisir et comme je ne suis pas sûr d'une minute, je ne perdrai pas une heure.

KEY TO TRANSLATION

GOOD RESOLUTIONS

If I get up late and dawdle (drag) all day, I shall hardly begin my work at night; but, I shall go to bed early, I shall get up early, and I shall obtain by that means health, wealth, and wisdom. I shall strive to be industrious, so that I may never have to fear want. It is not necessary that I should find a treasure, nor that a rich legacy should come to me; my activity will suffice me. I shall work from this very day, for I do not know whether I shall not be prevented from (doing) it to-morrow. I shall blush to do nothing when I have so much to do for myself, for my family, for my country. I shall take up my tools without mittens, and I shall remember that a gloved cat catches no mice. Perhaps I shall sometimes feel my arm too weak; but I shall hold fast, and I shall triumph over all obstacles. I shall make good use of my time, because I wish to win leisure, and as I am not sure of a minute I shall not lose an hour.

FORTY THOUSAND BARRELS OF OIL A DAY

LAKE VIEW GUSHER, IN CALIFORNIA, WHICH REACHED A HEIGHT OF OVER 300 FEET, AND POURED OUT OIL AT THE RATE OF OVER 40,000 BARRELS A DAY

The Source and Nature of Petroleum. Inorganic and Organic Theories. How Petroleum was Formed. The Nature of Petroleum Beds.

PETROLEUM

PETROLEUM, a Latin term meaning rock oil, is a general name for a wide variety of kindred mineral substances, ranging from wholly opaque to transparent, from semi-solid to extremely fluid, and from odourless to agreeably aromatic or highly offensive, all combustible, but with very different degrees of inflammability, and only in rare instances fit for use in any way without previous treatment.

The Petroleum Act, 1871 (34 and 35 Vict., ch. 105), which is still in force, except as to the standard of flash-point, and the mode of testing [see Methods of Testing, in a later chapter], defines *petroleum* in the following words: "For the purposes of this Act the term 'petroleum' includes any rock oil, Rangoon oil, Burma oil, oil made from petroleum, coal, schist, shale, peat, or other bituminous substance, and any products of petroleum, or any of the above-mentioned oils; and the term 'petroleum to which this Act applies' means such of the petroleum so defined as, when tested in the manner set forth in Schedule I. to this Act, gives off an inflammable vapour at a temperature of less than 100° of Fahrenheit's thermometer." It will thus be seen that the legal definition of petroleum is a wide one, embracing liquid products, such as coal-tar, and the solid product, paraffin, which are not "petroleum" in the commercial acceptation of that term. The reference to Rangoon oil and Burma oil doubtless had its origin in the circumstance that shortly before the Act was passed the produce of the Burma oil-fields was in small quantities brought to this country, petroleum having previously been imported only from the United States. The name of Rangoon oil was derived from the port of shipment, "Rangoon oil" and "Burma oil" being two names for the same product. Petroleum now comes to the United Kingdom from many other countries, and there is less reason for retaining the specific mention of Rangoon oil or Burma oil than for specifying Russian oil or the oils of Rumania and Borneo.

Crude Petroleum Oils. Crude oils, as collected, invariably consist of mixtures of several allied compounds, with, not infrequently, other substances, either dissolved in them, or mechanically enclosed and retained in suspension. They may be roughly classified as illuminating oils and fuel oils, according to the preponderance of one or other of these distinct groups of compounds in the natural admixtures, or in blends resulting from indiscriminate collection. The crude oils are further divided into asphalt-base and paraffin-base oils, according to the nature of the more solid matter held in solution by the more fluid, and determining the quality and use of the residue left on distilling off the lighter oils. The paraffin-base oils must not, however, be confounded with the ordinary burning oil (kerosene or paraffin oil), as the latter is largely made from asphalt-base crude oil. Petroleum was at one time called coal-oil, partly because a kindred substance could be prepared by distillation from coal, but chiefly from a mistaken idea that, being combustible, it must necessarily be derived in some unexplained way from coal seams. The term fell into disuse when it was found that not only did no such relation exist, but that oil-bearing rocks and coal rarely occur in the same geological series of strata.

The Origin of Petroleum. Much controversy has arisen upon the origin of these various compounds, some contending for their production by purely chemical action, deep in the unknown interior of the earth, and their ascent as vapour to be cooled and reduced to fluid or solid nearer the surface.

The distinguished Russian chemist Mendeléeff [see pages 442 and 710] gave the weight of his authority to the view that petroleum is of inorganic origin. The great density of the earth, the well-known presence of iron carbide in meteorites, as well as of iron in the solar system, as shown by the spectroscope, and the presence of iron in basalts and other eruptive rocks, were adduced by him as powerful arguments in favour of the assumption that the interior of the earth contains large amounts of iron, whether combined with carbon or not. Proceeding upon this assumption, he ascribed the formation of petroleum to the action of carbide of iron at high temperatures in the interior of the earth upon water which has penetrated through fissures produced in the earth's crust by the elevation of mountain chains or other changes of structure which have occurred.

On the other hand, the equally illustrious French chemist Berthelot [see pp. 310 and 442], accepting the hypothesis that the interior of the earth contains free alkali metals, ascertained by experiment that when carbonic acid or an earthy carbonate acts upon the alkali metals at a high temperature in the presence of water-vapour, chemical changes occur, which result in the production of hydrocarbons similar to those of petroleum, the exact composition of the hydrocarbons varying with the temperature. He therefore expressed the view that petroleum may have been produced by the infiltration of water containing carbonic acid gas into the interior of the earth, where it would be brought into contact with the alkali metals at an elevated temperature, and under great pressure, with the production of both liquid and gaseous petroleum.

Neither of these hypotheses is tenable, in view of the facts of the geological structure and composition of the rock-beds constituting the oil-bearing series in any part of the world.

Theories of Organic Origin. Two other schools exist of disputants on the origin of petroleum, each having amassed a sufficient body of evidence in support of animal origin in one case, of vegetable derivation in the other, to convince its partisans that the view propounded, if not of universal applicability, holds good in at least the great majority of oil-fields. The vast quantities of animal and vegetable remains stored in limestones and clays of various geological periods, and the legitimate assumption that where the rocks are not so rich in fossils their absence is due to want of preservative conditions rather than deficiency of life at the time of formation, indicate an ample supply of organic material at all periods of the

earth's history, as represented by stratified deposits; its decomposition generally, and its conversion into petroleum more rarely, being dependent on the conditions prevalent at the time and place of embedding in the strata, while the subsequent upheavals and removals of vast masses of material (to constitute the newer deposits) would tend to waste much of the earlier-formed oil, traces of which remain as asphalt or other bitumen, even in rocks of extreme antiquity, and in nearly every country in the world. As the adherents of the hypothesis of vegetable origin base their views generally on observations taken in different regions from those referred to by the exponents of animal origin, there is every probability that both schools are right in the main thesis, though wrong in insisting on its universality. The animal remains of the Ohio limestones have produced a different oil from that of the vegetable matter embedded in the somewhat later sandstones of the adjacent State of Pennsylvania. In each region, and for each geological period, the chief or sole factor is to be determined independently, and in many cases both animal and vegetable remains may have been contributory to the same store of petroleum.

Proof of Organic Origin. The most noted exponents of the view that petroleum is solely or mainly of animal origin are Höfer and Engler. In a series of experiments the latter obtained, by the distillation of menhaden (fish) oil at a high temperature and under considerable pressure, a product resembling petroleum. The distillate yielded by fractionation a lighting oil which was described as indistinguishable from commercial kerosene, and this statement the author of these articles, having received a sample of the product many years ago from Professor Engler, is in a position to confirm.

Oil is still being formed in various parts of the world, in some places from animal, in others from vegetable remains, though it is not known that any great bulk of it is produced, or any whatever preserved. For such storage the production must necessarily take place under conditions precluding the possibility of observation, and beyond the range of our present knowledge to imagine with any approximation to definite conception.

Bitumen, or some similar residue of evaporated petroleum, occurs, as we have seen, in even the oldest rocks, but oil of commercial value first appears in those of the Silurian epoch [see GEOLOGY]. From this early period down to nearly the present era valuable oil-fields occur, at one point or other, in every division of the geological series. Probably the Miocene period was the richest in petroleum-forming conditions, a magnificent birthday endowment for the human race, then in the earliest stages of its biped evolution.

Mode of Occurrence of Petroleum. Two classes of rock combine to furnish the vast and ever-increasing quantity of petroleum annually consumed. These are coarse sands (or sandstones) and crystalline limestones, both of open, porous texture, the one consisting of grains of sand or larger fragments of stone, the other of crystals of carbonate of lime or of the mixture of carbonates of lime and magnesia known as dolomite. In the interstices between the grains or crystals, and in other cavities and fissures, the oil is stored, sometimes under great pressure, shut in by beds of impervious clay or shale, to be discharged as a fountain or "spouter" when the protective covering is pierced by a borehole.

The bending of the originally horizontal beds into arches and troughs by lateral pressure as the cooling globe shrinks in the course of ages and the more compressible rocks are squeezed into such folds, has, in many oil-fields, the beneficial effect of collecting all the water that may have remained from the time of original formation, or have penetrated subsequently, in the troughs, and the gas (which accompanies nearly all petroleum) in the crowns of the arches, leaving the oil on the flanks of the folds, with the cushion of gas to afford the desirable pressure, and the water-seal, as in a trapped drain, to prevent escape downwards.

The arches are termed *anticlinals* (sloping oppositely), and the troughs *synclinals* (sloping together), terms of constant use in the discussion of oil-fields, in that they connote the productiveness or barrenness (in respect of oil) of successive portions of the country thus constituted. As the course of the rivers and minor streams, carving out hill and dale, is largely independent of these bendings of the rocks, effected in ages long past, an anticlinal arch may be, and often is, the floor of a valley, and a synclinal trough the ridge of a hill; the terms refer to the slope of the beds of rock, not to that of the surface, which may be quite level, or fall in a wholly different direction.

In many of the most notable oil-fields salt occurs, either as rock-salt or as strong brine, in close association with the petroleum, pointing to some obscure relation between the accumulation of salt and the original conditions under which oil is formed. It may, however, be due merely to the similarity of surroundings essential for the preservation of either substance in undiminished quantity—namely, the presence of an impervious cover to keep the oil from escaping, and the salt from the access of water. Both rock-salt and brine frequently occur with little or no trace of associated petroleum, but salt, as the more universally distributed substance, generally lingers under the cover which protects oil-deposits.

The Relation of Mud Volcanoes to Petroleum. Mud volcanoes are not infrequent accompaniments of petroleum, and by a supposed connection with true volcanic action have helped to confirm the untenable view of the purely chemical origin of oil. They are, in fact, springs of water, either pure or mineralised, cold or tepid, which, rising through apertures in fine clayey material, carry up mud in such quantity as to produce around the outlet a cone resembling that of a miniature volcano. Such cones are of all sizes, from a fraction of an inch to many yards in height, in proportion to the force of the current which has produced them. They sometimes occur with no trace of petroleum, being merely natural "artesian" wells. When occurring in oil-fields, the speed and carrying power of the current is generally enhanced by gas escaping under pressure, and the ejection of the semi-fluid mud is spasmodic, the pent-up gas, as it nears the surface, forcing a way through the last few inches in bubbles that burst with a sudden "plop," often creating a vibration perceptible for a long distance off. The spontaneous or accidental ignition of the gas of the larger cones increases the superficial resemblance to true volcanic eruptions; but, apart from the disproportion in size, there is no similarity in essential particulars between these cold-watery ejections and the molten outpourings of real volcanoes. Only where the region contains beds of soft, mud-forming material are these cones produced; the phenomenon is unknown in areas composed of more solid rocks.

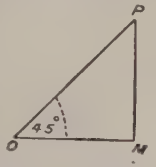
BOVERTON REDWOOD

Ratios of 45°, 30°, 60°, 90°, 180°, 0°. Relations between the Ratios of an Angle and its Complement and Supplement. Compound Angles.

RIGHT-ANGLED TRIANGLES

18. The Trigonometrical Ratios of Certain Well-Known Angles. The ratios of a few angles which are sub-multiples of two right angles can easily be found.

The Ratios of 45°. Let $\angle POM = 45°$. In one of the lines bounding the angle take any point P and draw PM $\perp$ to the other bounding line. Then, since the $\angle$s at O and M make up one and a half right angles, the remaining $\angle$ OPM must be half a right $\angle$. Hence, MP = OM = m, say. Therefore, if OP = x, we have $x^2 = m^2 + m^2$ (*Prop.* 34).



$$\therefore x = m\sqrt{2}.$$

Hence,

$$\sin 45° = \frac{MP}{OP} = \frac{m}{m\sqrt{2}} = \frac{1}{\sqrt{2}}.$$

$$\cos 45° = \frac{OM}{OP} = \frac{m}{m\sqrt{2}} = \frac{1}{\sqrt{2}}.$$

$$\tan 45° = \frac{MP}{OM} = \frac{m}{m} = 1.$$

The Ratios of 60° and 30°. Let OPQ be an equilateral Δ. Then each of its $\angle$s is one-third of 180°, *i.e.*, 60°. Draw PM $\perp$ to OQ. Then

Δ OMP = Δ QMP (*Prop.* 19).

$\therefore \angle$ OPM = $\angle$ QPM,

so that each of them is 30°. Also OM = QM, and OM is therefore half of OQ.

$\therefore$ if OM = m, we have OP = $2m$,

and $MP^2 = OP^2 - OM^2$ (*Prop.* 34)

$= 4m^2 - m^2 = 3m^2$.

Hence, $MP = m\sqrt{3}$.

$$\therefore \sin 60° = \frac{MP}{OP} = \frac{m\sqrt{3}}{2m} = \frac{\sqrt{3}}{2}.$$

$$\cos 60° = \frac{OM}{OP} = \frac{m}{2m} = \frac{1}{2}.$$

$$\tan 60° = \frac{MP}{OM} = \frac{m\sqrt{3}}{m} = \sqrt{3}.$$

Also, since $\angle$ MPO = 30°, we have

$$\sin 30° = \frac{OM}{OP} = \frac{m}{2m} = \frac{1}{2}.$$

$$\cos 30° = \frac{MP}{OP} = \frac{m\sqrt{3}}{2m} = \frac{\sqrt{3}}{2}.$$

$$\tan 30° = \frac{OM}{MP} = \frac{m}{m\sqrt{3}} = \frac{1}{\sqrt{3}}.$$

The Ratios of 0°, 90° and 180°. We have already seen, from Arts. 15, 16, 17, that

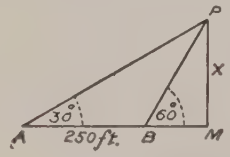
$\sin 0° = 0$, $\cos 0° = 1$, $\tan 0° = 0$.
$\sin 90° = 1$, $\cos 90° = 0$, $\tan 90° = \infty$.
$\sin 180° = 0$, $\cos 180° = -1$, $\tan 180° = 0$.

The values of the ratios thus found should be known by heart. Any required ratio is best remembered by thinking of the lengths of the sides of the triangles from which they are obtained. For example, if the value of cos 60° is required, think of the equilateral triangle, and it will easily be remembered that OM is half of OP, and therefore $\cos 60° = \frac{1}{2}$. In the same way, if sin 90° is required, think of the figure of Art. 15, and remember that as the angle approaches 90°, MP becomes nearer and nearer in length to OP, until finally $\sin 90° = \frac{OP}{OP} = 1$.

19. Solution of Right-angled Triangles. The angle which the straight line joining the observer's eye to a distant point makes with the horizontal is called the *angle of elevation* or the *angle of depression* of the point, according as the point is *above* or *below* the observer.

The Trigonometrical Ratios are, in most cases, incommensurable numbers. Their approximate values have been found for all angles, differing by 1′, from 0° to 90°. It will be seen later that this is sufficient to determine the ratios of any angle whatever. [Chambers' Mathematical Tables. 3s. 6d.]

EXAMPLE 1. The angle of elevation of the top of a tower is 30°. From a point 250 feet nearer the foot of the tower the elevation is 60°. Find the height of the tower.



Let PM represent the tower, and let A, B be the points of observation, so that

AB = 250 feet.

Let PM = x feet, BM = y feet.

Then $\frac{MP}{BM} = \tan 60°$,

and $\frac{MP}{AM} = \tan 30°$.

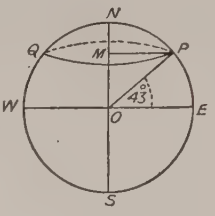
Hence, $\frac{x}{y} = \sqrt{3}$ . . . . (1)

and $\frac{x}{y + 250} = \frac{1}{\sqrt{3}}$ . . . . (2)

The solution of these two equations gives $x = 216{\cdot}5$ feet.

EXAMPLE 2. Find the distance travelled in an hour, in consequence of the earth's rotation, by a person situated in latitude 43° ; given that

cos 43° = ·73135, and that the earth's radius = 4000 miles.



Let NS be the earth's axis, and P a point in latitude 43°, *i.e.*, ∠EOP = 43°. Draw PM ⊥ to ON. Then, owing to the earth's rotation, P describes a circle about M as centre. Also

$$\frac{MP}{OP} = \cos MPO = \cos EOP = \cos 43°.$$

$$\therefore MP = OP \cos 43° = 4000 \times \cdot 73135 \text{ miles} = 2925 \cdot 4 \text{ miles.}$$

Hence, in one hour, the point P travels $\frac{1}{24}$ of the ◯ce of the ⊙ which P describes,

$$= \frac{1}{24} \times 2\pi \,.\, PM = \frac{2 \times 22 \times 2925 \cdot 4}{24 \times 7} \text{ miles} = \underline{766 \text{ miles.}}$$

20. Complement and Supplement of an Angle. We shall now prove that

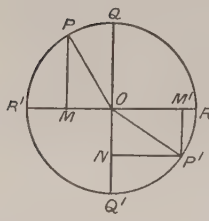
(i.) The sine of an angle = the cosine of its complement.

(ii.) The sine of an angle = the sine of its supplement.

(iii.) The cosine of an angle = − (the cosine of its supplement)

whatever the magnitude of the angle may be.

(i.) Let OP, starting from OR, trace out the angle A; and let OP′ trace out 90° − A, *i.e.*, let it first trace + 90° by turning in the positive direction up to OQ, and then turn back from OQ through the ∠QOP′, equal to − A.



Thus, in whatever quadrant OP lies, the ∠ROP which OP describes from OR is always equal to QOP′ which OP′ describes from OQ in the negative direction. Therefore P′N must always be equal to PM in magnitude, *i.e.*, OM′ = PM in magnitude. Also, by drawing figures in which OP lies in any other quadrant than the one shown, it will be seen that when P is *above* ROR′, P′ is to the *right* of QOQ′, and when P is *below* ROR′, P′ is to the left of QOQ′. Hence PM and OM′ always have the *same sign.*

∴ for all values of the ∠A we have

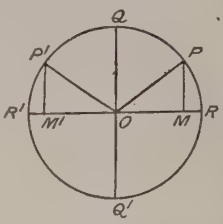
$$\frac{MP}{OP} = \frac{OM'}{OP'},$$

i.e., sin A = cos (90° − A);

or, the sine of an angle = the cosine of its complement.

(ii.) As before, let one revolving line OP trace out the ∠A, and let the other, OP′, trace out 180° − A, by turning first into the position OR′ and then back through R′OP′, equal to − A.

Hence, since the angle which OP describes from OR is always equal to the angle which OP′ describes from OR′ in the opposite direction, we have M′P′ always equal to MP in magnitude. Also P and P′ must always be both on the same side of ROR′, so that MP and M′P′ have the same sign.



$$\therefore \frac{MP}{OP} \text{ is always equal to } \frac{M'P'}{OP'},$$

i.e., sin A = sin (180° − A).

(iii.) Again, OM and OM′ are clearly always equal in magnitude, and on whichever side of QOQ′ the point P lies, the point P′ will lie on the other. Hence, OM and OM′ are always of opposite sign.

$$\therefore \frac{OM}{OP} = -\frac{OM'}{OP'},$$

i.e., cos A = − cos (180° − A).

21. In the same way, the student can easily prove for himself such formulæ as

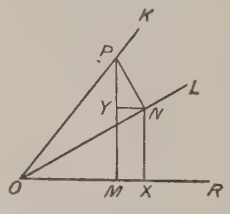
sin A = − cos (90° + A).
cos A = sin (90° + A).
sin A = − sin (180° + A).

22. Trigonometrical Ratios of Compound Angles. The "A, B" Formulæ. To prove that

sin (A + B) = sin A . cos B + cos A . sin B

and

cos (A + B) = cos A . cos B − sin A . sin B.



Let ROL be the angle A, and LOK the angle B. Then ROK is the angle (A + B). In OK, one of the arms of this angle, take any point P, and draw PM, PN ⊥ to OR, OL. Draw NX, NY ⊥ to OR, PM. Then, since ∠s PMO, PNO are right ∠s, ∴ a ⊙ on OP as diameter will pass through M and N (*Prop.* 39, *Cor.* 1). ∴ ∠s MPN, MON are in the same segment, and therefore are equal (*Prop.* 40). Hence ∠MPN = ∠A. Then,

$$\sin (A+B) = \frac{MP}{OP} = \frac{XN + YP}{OP} = \frac{XN}{OP} + \frac{YP}{OP}$$
$$= \frac{XN}{ON} \cdot \frac{ON}{OP} + \frac{YP}{PN} \cdot \frac{PN}{OP} \text{ (Art. 73, page 93)}$$
$$= \sin ROL \,.\, \cos LOK + \cos MPN \,.\, \sin LOK$$
$$= \sin A \,.\, \cos B + \cos A \,.\, \sin B.$$

Again,

$$\cos (A+B) = \frac{OM}{OP} = \frac{OX - YN}{OP} = \frac{OX}{OP} - \frac{YN}{OP}$$
$$= \frac{OX}{ON} \cdot \frac{ON}{OP} - \frac{YN}{PN} \cdot \frac{PN}{OP}$$
$$= \cos ROL \,.\, \cos LOK - \sin MPN \,.\, \sin LOK$$
$$= \cos A \,.\, \cos B - \sin A \,.\, \sin B.$$

H. J. ALLPORT

The Natural Regions, Products, and Trade of the Temperate Lands of the Far East, of the Southern Hemisphere, and of North America.

NATIONS AS TRADERS

CHINA proper with its many millions, has to be distinguished from the belt of its dependencies —Tibet, mainly an icy waste except in the south-east; Chinese Turkestan, a desert fringed with small oases, and valleys with fruit trees, cotton, etc.; Mongolia, a desert of poor steppe land, with camels and horses, and having a slightly more fertile margin; Manchuria, resembling Mongolia, in the west, but fertile and prosperous in the centre and east. Except the richer parts of Manchuria, these dependencies are of little economic importance.

The Richer Areas of Southern China. China proper consists of a hilly south and west, and a flatter north. The south has wooded hills, producing lacquer, vegetable wax, leaves for silkworms, tea; while rice, cotton, sugar are cultivated in the irrigated valleys. This region may be divided into five divisions:

(1) The plateaus of Yunnan and Kweichau, rich in gold, silver, copper, coal and iron, with outlets to Red River of Tongking, the Yangtse Kiang, and chiefly to the Si Kiang.

(2) The Si Kiang Valley, with Canton as its capital, and outlet on the delta. Near it is the British island of Hongkong, the great shipping junction of the Far East.

(3) The Eastern Highlands, with a port at the mouth of each valley, Swatau, Amoy, Fuchau (at the mouths of the eastern Min), Ningpo, and Hangchau.

(4) The Lower Yangtse Valley, which is partly in the plains, but its tributaries, the Kan, Siang, and Han, come from hilly lands rich in minerals, especially anthracite and iron, in the Siang basin. This is the valley the railway from Canton to Hankow will follow. Shanghai, on the Wusung, near the mouth of the Yangtse, is the port to which most ocean steamers come, but they can ascend past Nanking to Hankow, at the mouth of the Han, where many routes converge [see also page 2664]. Navigation is possible to Ichang, at the mouth of the gorges, where the river is very rapid, though not enough to prevent small steamers reaching beyond the gorges to Chungking. This is the port of

(5) The Red Basin of Sechwan [see page 2664], the capital of which is Chengtu, on a very fertile, irrigated plain. Coal, iron, salt, and other minerals abound.

The Rich Lands of Northern China and Manchuria. The rich lands of Northern China and Manchuria have a much colder winter than the south, the people are hardier, and even more industrious. The fertile soil, much of it loess, is irrigated and cultivated in the most careful manner, producing millets and pulses. Silk and tea are mainly confined to the south.

We may divide this district into:

(1) The plains south of the Hwang Ho, among the richest lands in China, crossed by the Grand Canal from south to north in the east, and by the railway from Hankow to Peking in the west, and from Kaifeng, where the Hwang Ho leaves the mountains, to Shanghai, near the mouth of the Yangtse.

(2) To the north-east rises the Shangtung peninsula—a hilly land with rich coalfields. Kiauchou (Japanese) is chief outlet. Chifu is the northern port and Wei-hai-wei a British station in the east of this region.

(3) In the north-west the hilly provinces of Shensi and Kansu, by which the route to the centre and west of Asia passes viâ Singan on the Wei and Langchau on the Hwang Ho. Tobacco is important in Kansu.

(4) The mountains north of the Hwang Ho in Shansi, which are among the richest mineral regions of the world, with anthracite and bituminous coal, iron and copper, which are all now being tapped and will rapidly be exploited as railways are built.

(5) The rich alluvial plains of Northern China fringing the Gulf of Pechili, with Peking to the north, and Tientsin its port.

(6) The plains and hills on East Manchuria, with much more severe winters, shorter, cooler, and drier summers; rich in beans, and capable of growing maize and wheat. The hills are wooded, and contain rich minerals, including gold, as yet little exploited. The railway runs northward from Port Arthur, by Niuchwang (the port), Mukden (the capital), to Harbin, where it joins the Russian Siberian line to Vladivostok.

Industrial Condition of China. We have seen that China is still essentially an agricultural country. It produces food for nearly 400,000,000 people, and imports very little. The needs of such a population are great, for clothing, dwellings, etc. Hence the building of houses, making of cloth, clothes, and agricultural implements are all important occupations. The manufactures, however, are still almost all domestic. An immense internal trade is carried on, but is much hampered by bad means of communication, except on the great waterways, of which the Imperial Canal and the Yangtse are the chief. The numerous customs and other tolls and the monetary system of China also hamper trade. The official coinage is confined to copper cash, of which 35 go to the penny, and most exchanges are effected by silver, which is weighed. The value of one tael weight (a Haikwan tael) fluctuates considerably: at present it equals $36\frac{5}{8}$d.

Railways in China. The era of railway construction, and the development of mining and of manufacturing by modern mills, which have just begun in China, are destined to effect an economic revolution in a much shorter time than in Europe, and of far greater importance than in Japan. The railway built from Peking to Tientsin, Taku, and Manchuria, from Peking by Paoting to Hankow, which is being extended to Canton; the line round Shangtung from Kiauchou; from Kaifeng to Shanghai; those projected up the Hwang-Wei, Yangtse Kiang, and Si Kiang; the Yunnan railway to Tongking, are among the most important which will bring the greatest cities of the interior in close touch with each other and the outer world, and will tend to develop a great trade.

Present Foreign Trade of China. The trade of China in the year 1912 was as given in the following table.

In Haikwan taels (3s. 0§d.)			
Imports	Thousands of taels	Exports.	Thousands of taels
Cotton goods ..	144,089	Silk, raw and manufactured ..	93,558
Opium	47,707	Tea	33,778
Kerosene oil ..	24,846	Beans	23,374
Sugar	23,912	Beancake	17,643
Metals of all kinds	18,242	Raw cotton	17,021
Rice	11,680	Oil (bean, ground-nut)	14,145
Fish	10,551	Hides, cow and buffalo	8,769
Coal and coke ..	8,221	Straw braid	7,644
Woollens and yarn	7,849	Skins (furs) and rugs	6,428
Matches	6,985		
Machinery	5,792		

Silk, tea, and cotton, but little produced in Europe, are among the chief exports. The cultivation of beans has assumed much importance in recent years, and during the last decade the value of the exports of beans and beancake has increased fourfold. On the other hand, the tea trade has diminished greatly since Indian and Ceylon competition came into play.

The following table shows the amounts sent to the United Kingdom from China, including Hongkong and Macao:

Year.	lb.	Value £
1890	73,743,000	2,813,000
1895	40,084,000	1,431,000
1900	21,316,000	688,000
1905	15,024,077	504,147
1910	18,914,720	650,463
1912	20,947,029	798,929

The following table shows the chief countries with which China trades, and the value of the trade done with them:

In Haikwan taels (3s. 0§d.)			
Country	Imports from	Exports to	Total
Hongkong ..	147,801	103,384	251,185
Japan and Formosa	91,017	55,262	146,279
Continental Europe (except Russia)	37,471	81,066	118,537
United Kingdom	74,856	15,900	90,756
United States..	36,198	35,050	71,248
Russian Empire	21,233	45,197	66,430
India	46,646	7,573	54,219

The Hongkong trade is with many countries. Of course, it includes more than the China trade, but an analysis of it will give some indication of how the great values entered in the trade of China under Hongkong are to be distributed.

Thus the interests of the British Empire in Chinese commerce are by far the greatest of those of any foreign Power.

Japanese Empire. The Japanese Empire for trading purposes may be divided into Japan and Formosa. The latter island is noted chiefly for camphor and tea. Gold, silver, and copper are worked.

Japan has been described on pages 2797 and 4521. Its trade may be gathered from the following table for 1912:

In yen (2s. 0½d.)			
Imports	Yen	Exports	Yen
Raw cotton ..	200,823,000	Silk, raw	150,321,000
Metals and metal manufactures	72,529,000	Silk tissues ..	34,998,000
Machines and machinery ..	31,428,000	Silk waste ..	10,543,000
Rice	31,344,000	Cotton yarns	53,680,000
Oilcake	29,609,000	Cotton manufactures	28,246,000
Wool and woollen yarn ..	24,664,000	Copper.. ..	24,923,000
Sugar	16,168,000	Coal	20,284,000
Kerosene oil ..	12,433,000	Straw plait ..	17,337,000
Sulphate of ammonia ..	12,164,000	Tea, green ..	12,849,000
Cotton goods and yarn	11,790,000	Matches	12,161,000
Soya beans ..	8,270,000	Sugar	8,477,000

It will be noticed how large a share the industrial life of Japan is playing in its trade. Raw materials, foods, ironwork, and machinery are the chief imports; and while raw silk, tea, and minerals are important exports, manufactured silk and cotton and matches are also large items in the goods sent abroad. Japan has progressed farther than China in the development of modern manufacture and commerce. Its resources are nothing like so great as those of China, but we can gain a slight idea of what may happen in China in the near future by studying the existing economic position of Japan.

Countries with which Japan Trades. The comparison of the values of imports and exports for 1912 in the table below shows how Japanese trade relations are developing.

Value in yen (2s. 0½d.)			
Country	Imports from	Exports to	Total
United States..	127,015,000	168,708,000	295,723,000
China	54,807,000	114,823,000	169,630,000
Kwantung Province ..	25,707,000	27,544,000	53,251,000
India	134,741,000	23,648,000	158,389,000
United Kingdom	116,146,000	29,791,000	145,937,000
Germany.. ..	61,075,000	13,487,000	74,562,000
France	5,421,000	43,871,000	49,292,000
Hongkong ..	881,000	28,712,000	29,593,000
Dutch Indies ..	19,063,000	4,343,000	23,406,000
Australia.. ..	12,791,000	8,628,000	21,419,000
Italy	803,000	18,412,000	19,212,000
Belgium	9,087,000	3,080,000	12,167,000
French Indo-China.. ..	10,643,000	349,000	10,992,000
Russian Empire	742,000	6,082,000	6,824,000

The United States takes tea and raw silk, and in return sends manufactured goods, raw cotton, and wheat. The United Kingdom and German trade is largely one of manufactured goods sent to Japan, from which is taken a very much smaller value of produce. The trade of France and Italy presents a very great contrast, for it is one in which raw silk from Japan to Europe plays a great part, while the exports from these countries to Japan are very small. On the other hand, Japan gets from India half of its raw cotton imports, and also much rice from Burma. The Japanese trade is thus the most complex we have yet studied.

The Three Types of Land already Studied. We have now examined three different types of countries from the commercial point of view: (1) The poor lands of the icy and arid deserts

and their margins, of little commercial value save for mineral and animal products; (2) the rich vegetations of the hot, wet forests and bordering savanas, largely self-sufficing, only here and there exploited for trade purposes, mainly where plantations have been formed under European supervision; (3) the rich lands with regular seasons—dry winters and wet summers, with large alluvial lands easily flooded and cultivated, with a long civilised history, with well-developed internal trade, hindered only by lack of easy communication, which is gradually being overcome. In India, European direction has introduced modern means of transport, but the exploitation of the country is in native hands; and while European capital has been sunk in factories, these are not all so financed, and are worked mainly by native labour.

In Japan, the European factor has been less important, and the stage of industrial evolution is beyond that of India. It is likely to be pushed farther almost entirely by the Japanese themselves. China is on the point of adopting all the more modern methods of production and communication, and it possesses probably the richest resources and the most numerous and laborious population in the world. There we may expect to find in the future the most striking economic developments not directed by European energy.

The Three Types still to be Studied. We have now to turn to those lands, almost entirely in the temperate regions, in which Europeans live and control the economic life. Three types may be studied: (1) the countries where the rural occupations are everything and industrial pursuits yield a very small part of the wealth of the country—for example, the European settlements in the southern hemisphere, in Western Canada and United States, and Asiatic Russia are of this type; (2) countries such as Eastern Canada, Central and Eastern United States, and most of Europe, except the west and centre, where industrial development is of great and growing importance, but in which the rural populations are still of great significance in their trade; and (3) such countries as Germany, Switzerland, France, Holland, Belgium, and, above all, the United Kingdom, in which the industrial development has proceeded still farther, and forms the chief source of their commercial activity.

The Main Economic Divisions of Southern Temperate Lands. We may divide the south temperate lands according to temperature and rainfall into: (1) the eastern wet regions, with hot summers and warm winters; (2) the central and northern hot arid areas; (3) the eastern regions, with warm summers and cool winters and fair rainfall, mainly in summer; (4) the western regions, with warm summers and with cool winters, during which most of the rain falls (Mediterranean type of climate); (5) and (6) the small regions of cool summers and cold winters, with rain at all seasons, little in the east, heavy in the west.

The Warm, Wet, Eastern Regions of Summer Rains in the South. Immediately south of the tropic of Capricorn lie in the east regions with warm winters and hot, wet summers where growth is checked only by drought. A considerable part of this region is well wooded, yielding fair timber. In clearings and grassy patches can be grown, in the warmer parts, some of the produce of intertropical lands, such as sugar, coffee, cotton, and rice, but the chief cereals are maize in the moister and warmer and wheat in the drier and cooler parts. Tea, pineapples, arrow-root, tobacco, oranges, lemons, and many other fruits are among the other products of this type of region, which is to be found in Southern Brazil, Uruguay, Paraguay, and eastern Argentina north of the Plate in South America; in Natal, the eastern Transvaal, and Cape Colony in South Africa; and in eastern southern Queensland and New South Wales in Australia. These roughly correspond to China and Southern Japan in their climatic conditions and economic vegetation, but the human conditions are very different, for the population is nowhere very dense, and cultivation is largely for a foreign market.

Grassland Zone between the Wet Zone and the Desert. Between the wet, forested east and the arid and desert, or almost desert, centre and west stretches a grassy area, capable of cultivation in the east and round irrigated areas in the west. While in the east the plants already named appear, in the drier irrigated areas plants of Mediterranean type, such as vines, figs, peaches, flourish. The chief wealth of these regions, however, is the live-stock, cattle in the moister and sheep and goats in the drier parts, tended by men on horseback. The mineral wealth varies greatly in different areas, and can be studied most conveniently under each country.

Hot Arid Regions. The central and western hot arid regions consist of the margin of the southern deserts, and are of little value save when irrigated. The irrigated areas are (1) in the west of Argentina, near the base of the Andes; (2) small areas in Bechuanaland and the Karroos of South Africa; and (3) in extra-tropical Southern Australia and the adjoining portions of Queensland, New South Wales, and Victoria. Here, Mediterranean fruits, maize, and lucerne (alfalfa) are the chief products. The Mildura colony of Victoria uses water pumped from the River Murray.

Outside the irrigated region the lands produce a poor scrub, which feeds small numbers of sheep, goats, and ostriches. The value of the land can roughly be judged by the rainfall. This is well shown by the following table, taken from a paper by Mr. Willis, in the "Scottish Geographical Magazine" for 1887:

District	Number of sheep per sq. mile	Mean rainfall in inches.
South Australia, dry area..	8 to 9	8 to 10
New South Wales, dry area	96	13
New South Wales	640	20
Buenos Aires	2,603	34
Irrigated land in California growing lucerne, equal to about..	12,000	60 to 100

This record shows how a series of dry years must reduce stock by lowering the power of the land to support large numbers.

The Mediterranean Type of Land. The Mediterranean type of land in the southern hemisphere has warm, dry summers, similar to those of the regions just described. It differs from them in enjoying a fair, or even heavy, rainfall in late autumn, winter, or early spring. This means that the moisture comes in the coolest part of the year, when other conditions of growth are not so favourable. The hot summers allow of the cultivation of cereals and of such Mediterranean fruits as

the grape, fig, orange, pomegranate, and olive; and here, as in Europe, the Mediterranean realm is one of corn and wine and oil. When irrigation is possible, and the supply of water in summer is sufficient, this type of region is very fruitful, as is shown by the Californian figures of the last paragraph.

This type of region is found in (1) Central Chile; (2) south-west Cape Colony; and (3) south-west of Western Australia, south of South Australia, Victoria, and the North Island of New Zealand. In the south of Australia the products are mainly wheats and fruits, with a little timber.

Sir Charles Todd has made a valuable study of the relation of rainfall to crops. Taking the mean rainfall for the winter six months, and comparing the amount with the yield of wheat in bushels per acre over a series of years, he finds the following relation: The seven best years, with an average yield of 12·43 bushels per acre, had 18·47 in. of rainfall. The five next best years, with an average yield of 10·02 bushels per acre, had a rainfall of 15·28 in. Six bad years, with an average yield of only 6·61 bushels per acre, had so small a rainfall as 13·55 in. From this we may also infer that there is a steady proportional increase in the yield of wheat per acre from the drier to the wetter parts of these lands.

One compensation possessed by the drier areas is that the quality of the produce is usually excellent, and the hard wheats of these dry areas command higher prices. [See AGRICULTURE.] Many of the trees round the margin of the dry areas yield excellent hardwood, in particular the jarrah and kauri of South-western Australia. [See BUILDING.]

The Trade of the Mediterranean Type of Lands. Most of these regions do little more than support themselves, and some do not manage to do even that, as a study of statistical tables shows. The exports are mainly minerals, wool, hides, and ostrich feathers from South Africa; timber from West Australia; wines from South Australia; and dairy produce and wines from Victoria. In examining the statistical tables, it must not be forgotten that in the case of all, except Victoria, the produce of other regions is included in the returns, as political and natural geographical boundaries by no means coincide. The trade of Chile, for instance, is mainly in nitrates from the northern deserts, and in copper, silver, and iron. These are independent of climate, and, if we exclude them, wool is the only other export of much value.

Textiles and wearing apparel, machinery, railway plant, hardware, and articles of luxury are the chief imports to these lands. The smallness of the market, and the cost and scarcity of skilled labour, are the chief hindrances to the development of local manufactures on a large scale.

Typical Trade Returns for Warm Temperate Lands. Let us next examine the trade of Uruguay and Natal as types of the eastern lands of the warm temperate zones. In this case, in order to obtain values which may be compared, we shall not quote the actual values of the statistical tables, but calculate the percentage which the value of each group of products bears to the total value. This is a valuable method of comparing statistics which the student should accustom himself to use. The values can be calculated from the total trade which is given at the top of the column.

In Uruguay, the country is only beginning to be occupied, and as yet little is broken by the plough, so that cattle-rearing is the chief occupation. In

Uruguay, 1912 Total exports, £10,156,000	Per cent.
Live animals	2·1
Animal products	80·5
Agricultural products	3·5
Other	13·9

Natal, cattle and sheep are reared on the higher slopes, but the lower warm lands near the coast are partly cleared and cultivated, mainly by Indian coolie labour. The exports to the United Kingdom in 1912 amounted to £2,725,373, of which wool formed nearly 49 per cent., hides almost 12 per cent., and maize over 2 per cent. In New South Wales very similar climatic conditions prevail. The drier interior is pastoral, the wetter east of the higher plateau cultivated with wheat, but the lower slopes round the coast grow maize, etc. Here the European alone works, and a more energetic, prosperous, and homogeneous community is growing up. In New South Wales the wealth of coal and gold is much greater than in the other lands, and is extracted by modern methods. Manufactures are rapidly developing.

The Cooler Southern Lands. The cooler southern lands, with fairly constant rains, comprise (1) South Chile, (2) Tasmania, and (3) the South Island of New Zealand, which lie in the track of the westerly storm-winds. The rain suffices for dense forests on the western slopes of the mountains, which are as yet little exploited for their timber. In some of the upper grassy valleys cattle are kept, especially in New Zealand. The mineral wealth is a very valuable asset, especially coal and gold in New Zealand. The potentially rich fisheries are not much developed.

The eastern side of these lands is much drier, and a chinook or föhn wind effect is frequently recorded. In Patagonia the country is as yet little developed, save for a few sheep-runs and gold-mines. The Canterbury Plains of New Zealand are rich in grazing ground, where many sheep are fed. The mutton is sent in refrigerating chambers to Britain, to which the wool and hides are also exported. Part of the land is cultivated with wheat. In the extreme south and in the higher lands oats are grown.

The Trade of New Zealand. The trade of these lands is small, except in the case of New Zealand, the statistics for which, however, include the produce of the warmer North Island. The export of meat and dairy produce is of recent growth, owing to the modern methods of refrigeration.

Exports from New Zealand, 1913		Imports to New Zealand, 1913	
Wool	£7,105,000	Clothing and textiles	£4,349,000
Frozen meat	3,909,000	Iron, steel goods, and machinery	4,321,900
Butter and cheese	3,769,000	Paper, books, and stationery	870,000
Gold	1,345,000	Sugar	814,000
Hides, skins, and leather	1,085,000	Oils	556,000
Grain	743,000	Alcoholic drinks	531,000
Tallow	684,000	Tobacco and cigars	488,000
Kauri gum	401,000	Fruit	433,000
Flax	376,000	Coal	365,000
Other articles	1,536,000	Tea	320,000
		Other articles	7,311,000
Total	£21,770,000	Total	£20,976,000

This is a very remarkable trade for a population of a million people. It gives a very fair idea of the economic conditions in that part of the southern hemisphere which most resembles our own island home.

Economic Divisions of Temperate North America. The present economic development of the North American lands is at very different stages. North America has been much longer settled by Europeans than has Australia, and its resources have been much more systematically and energetically exploited than those of Argentina.

The *Physical Divisions* roughly correspond with the economic ones. Broadly, they consist of (1) the mountainous west, (2) the central plains, and (3) the highlands and coastal lowlands of the east. Climatic conditions control the subdivisions of the vast central plains into tundra, forest, wheat, maize, and cotton belts, and the drier uncultivated grasslands of the higher western plains. Mineral wealth and density of population are other factors which must be taken into account in the various subdivisions, each of which has its own natural products and its characteristic economic conditions.

The Western Mountains. The high plateaus and intermont plains on the east of the western mountains are of little economic importance, except for stock-raising. The centres of settlement are (1) round such irrigated areas as those of Utah, especially round Salt Lake City; (2) in the plains at the mountain base, where the waters of the snow-fed rivers are carried over the plains; and (3) in the mining centres, which are especially numerous in Colorado, Montana, California, Southern British Columbia, and Klondike. Gold, silver, copper, and lead are the most abundant minerals.

The western valleys of the western mountains are much more favoured climatically. The temperature is equable, and the rainfall is abundant and well distributed throughout the year north of California, while in that state the winter rains are sufficient, except in the extreme south, which gradually becomes more desert-like.

South-western British Columbia, Washington, and Oregon are penetrated by straits and inlets, which permit easy sea communication. The most important of these openings are Puget Sound, with the ports of Olympia, Tacoma, and Seattle, and the straits round Vancouver Island, with Victoria on Vancouver Island, Vancouver on Burrard Inlet, and New Westminster. The last two are outports of the Fraser basin. Prince Rupert, the terminus of one of the transcontinental lines, stands on an excellent natural harbour at the mouth of the Skeena River. Farther south are Portland and Astoria, on the Columbia River, the outlet of the wheatlands of the Willamette Valley.

The lumber yielded by the forests of giant Douglas pines, the salmon of the numerous rivers, and the mineral wealth—gold, silver, lead, and copper—of the interior find an outlet through these ports. Grain from the western plains is now being brought to them in increasing quantities by the Canadian Pacific, the Canadian Northern, and the Grand Trunk Pacific railways for shipment across the Pacific. Coal is a very important export, as it is uncommon on the eastern coast of the Pacific between Puget Sound and Central Chile. Local iron ore is being smelted round Puget Sound, and shipbuilding and engineering works are being constructed. The development of this region is likely to be great and rapid.

The Wealth of California. California has a much larger area of plain than the lands farther north. Its climate is of the Mediterranean type, with winter rains. Orange, lemon, and olive groves, vineyards, peach, apricot, apple, pear, and other orchards, fields of maize, wheat, and lucerne, many of them irrigated, form its chief sources of wealth. In 1850 there were not 100,000 inhabitants in this State, which is three times the area of England. Today there are 2,500,000. The discovery of gold in 1848 attracted adventurers from all parts of America and Europe. Since then over £300,000,000 of gold has been extracted, and in 1912 over £3,900,000 was obtained. Nevertheless, it is the agricultural rather than the mineral wealth which has led to the remarkable development of California. The absence of coal has retarded the industrial development, but electricity is now generated by water power, and petroleum is much used as fuel for industrial purposes.

California possesses one of the finest harbours in the world, at the entrance to which, known as the Golden Gate, is built San Francisco, with its 420,000 inhabitants. This is the chief port in the eastern Pacific, with steamship lines for all parts.

The Central Plains North of the Missouri and Ohio. Furs and lumber are the economic products of the tundra and forests. The latter industry is very important round the Great Lakes, the St. Lawrence and its tributaries, where lumber is sawn and made into joiners' work and wood-pulp for exportation. The grasslands and the forest clearings are cultivated with wheat, and towards the south with maize. In the drier west stock is raised on the natural "buffalo" grass. In the agricultural area hogs and cattle are fattened on maize and the offal from the flour-mills. Round the Great Lakes are rich supplies of iron and copper ore, and farther south are vast coalfields which supply power for many growing industrial centres. The St. Lawrence and the Great Lakes and the Mohawk-Hudson valley are the chief natural routes from the east to this area, which has other outlets across the Appalachians and down the Mississippi. Three aspects of the economic life of this area deserve more detailed study: (1) The Canadian conditions; (2) the agricultural belt of the United States, and the industrial development consequent on its needs, and (3) the metallurgic activities of the eastern portion and the mining on which it depends.

Canadian Commerce.—Exports. Let us once more turn to statistical tables, which will give us a clear conception of the most important aspects of Canadian commerce, derived as it is mainly from this region. The value of the exports from Canada in thousands of dollars ($1000=£206) for the three years 1903, 1912-13, 1913-14 is as in the following table.

Exports from Canada.	1903	1912-13	1913-14
Mining products	31,062	57,442	59,039
Fishery products	11,800	16,336	20,623
Forest products	5,300	43,255	42,792
Animals and their products	69,818	44,784	53,349
Agricultural products	44,624	150,145	198,220
Manufactures	51,714	43,692	57,443
Miscellaneous	84	97	121
Total	214,402	355,751	431,587

The 1913–14 figures may be further analysed as follows: Gold quartz accounted for $13,320,000, copper ore for $9,489,000, coal for $4,040,000, and

silver ore for $20,971,000. Of fresh and salt water animals and fish, lobsters were the most important, accounting for $3,691,000; codfish was valued at nearly $4,706,000, and salmon at $7,455,000. Of forest produce, unmanufactured timber was worth $42,743,000, and wood-pulp $6,364,000. Cattle were the most important animals, valued at $7,906,000. Hides and skins accounted for $9,262,000, leather for $3,213,000, and furs for $5,667,000. In the dairy industries, bacon was worth $3,763,000, butter nearly $309,000, and cheese (the most valuable of all) brought in over $18,808,000. Of the produce of the fields, wheat is the most important, accounting for $117,719,000, and for nearly $20,581,000 more in the form of flour. Oats are worth $13,379,000, while fruits amount to over $4,585,000. Of the manufactures, agricultural implements amount to $7,219,000, and iron, steel, and machinery to $4,155,000.

The minerals are from the western mountains and the maritime provinces. Salmon is obtained mostly from the western, the other fish from the eastern, waters. Of the other products from the regions more particularly under consideration, wheat is obtained from the central plains, with Winnipeg as its collecting and distributing centre. Dairy produce and cheese are almost exclusively from Ontario and Quebec, and fruits from the Niagara peninsula and Nova Scotia.

All these exports are carried mainly across the Atlantic. The St. Lawrence forms the chief outlet for this trade in summer. In winter, when it is frozen, Halifax, St. John, N.B., and the United States ports have to be used. In 1912–13 Montreal shipped over $85,000,000 worth; Quebec, $8,500,000; St. John, N.B., $25,500,000; and Halifax, $15,000,000, while Vancouver, on the Pacific coast, handled $11,000,000 worth. During the last five years 38 per cent. of the exports were to the United States, and over 48 per cent. to the United Kingdom. The West Indies, the next market on the list, took only 2 per cent.

Imports to Canada. The following table shows the nature of the imports. Over 65 per cent. of the revenue of Canada is derived from its Customs duties. The value is again given in thousands of dollars ($1000=£206):

Nature of Imports to Canada	1903	1910–1911	1912–1913
Agricultural produce ..	18,464	35,304	46,655
Animals and their produce	15,577	23,258	41,088
Fisheries produce	1,403	1,995	2,674
Forest produce	5,116	12,873	20,138
Manufactures	150,590	310,514	465,198
Mineral produce	20,317	44,020	65,820
Miscellaneous	22,318	33,985	33,940
Total	233,785	461,949	675,513

In 1913–14 the imports amounted to $650,746,000, of which manufactures formed the largest proportion. Of the manufactured articles, iron and steel are by far the most important, amounting in 1913–14 to over $119,000,000. A very large proportion comes from the United States, as do the imports of coal and coke, which are valued at $52,000,000. Cotton manufactures, which are next on the list ($37,000,000), enter from Great Britain under the preferential tariff, as do woollen goods, worth $31,000,000. Cotton-wool and waste ($8,000,000), free of duty, and tobacco ($7,000,000), also mainly duty-free, enter for the manufacturing centres of Montreal, Western Quebec, and the Lake peninsula. Sugar (over $17,000,000) and fruits (over $17,000,000) come largely from the West Indies. Wood manufactures, carriages, drugs and chemicals, oils, manufactures of silk, of jute and hemp, and of gutta-percha are important items in the import trade. The United States does more than any other country to supply Canada's needs, to the extent of 62 per cent. on the average of the last five years. The United Kingdom supplies less than 23 per cent., and Germany, France, and the West Indies come next in order.

The ports by which these imports enter are of interest. Montreal still heads the list with nearly $156,000,000; but Toronto comes next with over $121,000,000. Quebec has nearly $15,000,000, Halifax over $12,000,000, Ottawa slightly over, and St. John, N.B., a little under, $10,000,000, while Vancouver has $44,000,000.

The Central United States. As in Canada, the west of the United States is a ranching country, raising cattle and sheep. East of 100° W., the rainfall is sufficient for agriculture. Wheat is the staple crop in the north, and maize in the south. Most wheat is grown in the Red River valley and the Dakotas, but it is cultivated even south of the Ohio mouth. Much of the crop is forwarded to the Lake ports (Duluth, Superior, Chicago, etc.) and sent by the Great Lakes to Buffalo, where most of it is put on the rail for New York. Part of it goes by rail the whole way to the eastern and Gulf ports. An increasing amount is sent by rail across the Rocky Mountains to Puget Sound. The cost of transport has been extraordinarily diminished in America. To lessen its ratio to the value of the freight a large proportion of wheat is milled into the more valuable and compact form of flour. Minneapolis, where the Falls of St. Anthony supply water power, Superior, Duluth, Kansas City, and many cities farther east, are important milling centres.

Similar considerations of economy lead in the maize belt to the fattening of cattle and hogs on the crop raised. The stock and the cattle and sheep from the ranches are slaughtered and sent east as "chilled meat" in refrigerated trucks. Enormous quantities are "packed" or canned. The hides are made into leather. The wool and hair, bones, sinews, and even the blood and offal, are utilised in various ways. The mutton is sent mainly to the Eastern States, but much beef is exported. The chief meat-packing cities are Omaha and Kansas City on the Missouri, and Chicago. Formerly Cincinnati was the "Porkopolis" of the United States, and St. Louis rivalled Chicago. As settlers moved westwards new meat-cities grew up, but the old ones still retain a fair trade.

These regions need railway plant of all kinds, agricultural implements, and the clothing, luxuries, and other requirements of a population which is not, like many of the Old World peoples, self-supporting. The railway has been in many cases the precursor of settlement, for without it the settler could neither procure supplies nor send his produce to market.

The Industrial Region East of the Mississippi. A generation or so ago the now busy and populous region east of the Mississippi preserved the same characteristics as the region just described. Now all is changed. Coal is widely distributed and mined, and used at all the great and growing cities for their numerous and varied manufactures. Between Western Pennsylvania and Illinois are many oil and natural gas-wells,

which supply a valuable fuel. The petroleum is conveyed in pipes to Chicago, Pittsburg, Cleveland, Buffalo, New York, Philadelphia, Baltimore, and other cities. Iron ore and limestone occur in the Western Pennsylvania coal, oil, and gas field, with the result that this region has become one of the leading steel-making centres of the world. The local ore no longer suffices. Fortunately, iron ore is abundant round Lake Superior, whence it is shipped in giant "whale-back" steamers to Chicago and the ports on the southern shores of Lake Erie to be smelted. Much is carried by rail from Africa. Since their emancipation these negroes have still remained the chief cultivators of the ground. Nearly three-quarters of the raw cotton of the world is grown in this area. Most of it is shipped to Europe (half to England) and New England from Galveston, New Orleans, Mobile, Pensacola, Savannah, Charleston, Wilmington, and even Baltimore. The sugar and rice of the south are not much exported. The tobacco of the northern margin of this belt is exported, the great markets being Richmond (Virginia), east, and Louisville (Kentucky) west of the Appalachians.

THE BEGINNING OF THE INDUSTRIAL GREATNESS OF CHINA: A VIEW OF PART OF THE VAST HUNYANG IRON AND STEEL WORKS AT HANKOW

China has enormous resources of both coal and iron. Seventy miles from Hankow there exists one of the richest deposits of iron ore in the world, the amount on the surface being estimated at five hundred million tons.

to Pittsburg, the greatest iron and steel city in the world. Here, again, remarkably low rates of carriage have led to an extraordinary economic expansion. The ore is carried to the fuel because the fuel is near markets for the finished products.

The Central and Southern Atlantic Plains. The Central Plain south of the Ohio and the Southern Atlantic Plain is a hot region where cotton is the most important crop. Tobacco is grown in the north and sugar in the south. Throughout this region the labour problem, which is a difficulty in many hot lands, was formerly overcome by the importation of slaves, mainly

The Southern Appalachian coal and iron field has only recently been adequately exploited. Steel and iron are made round Birmingham (Alabama). A remarkable feature is the rapid development of the cotton manufacture of Atlanta and other manufacturing centres of the other States, but unhappily child labour is largely used to cheapen production and supply the necessary labour.

The New England Manufacturing Area One of the earliest English settlements in North America was on what is now known as the New England coast. Gradually the pioneers made their way inland across a rather poor highland

into the parallel fertile valleys. These diminished in agricultural importance with the opening up of the prairies in the west. The irregular shores of New England afford good harbours, but fishing and the building of ships with timber from the forested hills have both declined. The result is that New England has specialised in manufactures, a development rendered easier by the abundance of water power. With improved facilities of transport, coal is brought from Pennsylvania by sea and rail, while cotton is imported from the south and wool from the east oversea. Leather, boots, clothing, ironmongery, clocks, watches, and many other articles are manufactured.

Economically there is a marked tendency for the more skilled occupations to expand while those employing less trained labour pass elsewhere. The manufacture of coarser cottons has thus been transferred to the South Appalachians. The chief New England cotton centres are Lawrence, Lowell, and Manchester on the Merrimac River, Augusta and Waterville on the Kennebec, and other cities on the New England rivers, not far from the coast. Fall River, in Rhode Island, is also a seaport, and the consequent reduction in transport charges has made it the largest of all. Woollen factories are more widely distributed. Lawrence and Lowell are busy centres. Carpet-making is important at Lowell and Hartford. Lynn, Brockton, Haverhill, and other towns make boots and shoes and Waterbury watches. Worcester is a great engineering centre. There are many towns with varied manufactures, especially of ready-made clothing. Of these industrial centres Boston is the chief port, but it is cut off from the great western industrial and agricultural area by the Berkshire and other highlands of Western New England.

The Central Eastern Industrial Area. The central eastern industrial and commercial area is very important. The great inlets which penetrate to the "fall line" make admirable waterways to the manufacturing centres, which are grouped round the anthracite fields of Eastern Pennsylvania. Many large towns are noted for special industries, but in this area engineering, especially in Philadelphia and New York, is even more important than textile manufactures. Philadelphia is the chief locomotive and shipbuilding centre in America. Locomotives are also constructed at Paterson, near New York, Scranton, Richmond, and other centres. Ready-made clothing is an important industry in New York, Philadelphia, Baltimore, and other cities in the States.

The central eastern ports are Baltimore, Philadelphia, and New York, which have already been described on page 3165.

Exports and Imports of the United States. The exports of the United States are gradually altering in relative importance. Manufactured articles form a steadily increasing proportion of the exports. The figures for 1912–13 are, in round numbers:

Cotton, unmanufactured	$547,000,000
Iron and steel and manufactures thereof	304,000,000
Breadstuffs	211,000,000
Meat and dairy products	153,000,000
Copper and manufactures thereof	$143,000,000
Mineral oils	137,000,000
Wood and manufactures thereof	115,000,000
Coal	65,000,000
Leather and manufactures thereof	63,000,000
Tobacco and manufactures thereof	55,000,000
Carriages, vehicles, etc.	54,000,000
Cotton manufactures	53,000,000

The chief imports for 1912–13 are, in round numbers:

Coffee	$118,000,000
Hides and skins	117,000,000
Sugar	103,000,000
Chemicals, drugs, and dyes	99,000,000
Indiarubber	97,000,000
Raw silk	84,000,000
Fibres, vegetable and textile grasses, manufactures of	76,000,000
Cotton manufactures	66,000,000
Wood and manufactures of	61,000,000
Tin, in bars, blocks, etc.	53,000,000

Of the exports, 32 per cent. consist of finished manufactured articles, and an additional 17 per cent. of articles partly manufactured; 30 per cent. are raw materials for manufacture, and the remainder of the exports (21 per cent.) consist of foodstuffs, either raw or prepared. Owing to the increased home demand, the quantity of agricultural produce, especially wheat, available for export is gradually diminishing. Of the imports, 33 per cent. consist of raw materials for manufacture, and 20 per cent. of manufactured articles.

Countries with which the United States Trades. The United Kingdom is by far the best customer of the United States, and supplies most of its imports. Germany comes second in both capacities. The totals for the chief countries for 1912-13 are given in thousands of dollars in the subjoined table, which students can examine in greater detail.

Country	Exports to	Imports from	Total Trade
United Kingdom	597,150	295,564	892,714
Canada	420,148	121,723	541,871
Germany	331,684	188,963	520,647
France	146,100	136,877	282,977
Netherlands	125,909	38,180	164,089
Brazil	42,638	120,155	162,793
Japan	57,741	91,633	149,374
Mexico	54,571	77,543	132,114
India	15,108	116,178	131,286
Italy	76,285	54,107	130,392

The United States is a vast country, nearly as large as the whole of Europe, with a greater variety of climate and products, and with even greater mineral wealth. Consequently, we must compare the vast area for internal trade which exists in the United States with that of Europe. The same fact should be borne in mind when we compare the foreign trade of the United States with that of our own country or of any other single country in Europe. Within a very short time the United States' foreign trade ought far to surpass that of any other country. This, however, need give us no cause for patriotic misgivings. The world's wealth of purchasing is not a fixed and exhaustible quantity, but one that is ever increasing; and we may view the success of other countries without alarm so long as our trade shows no signs of shrinkage.

FAMOUS EXAMPLES OF ART METAL WORK

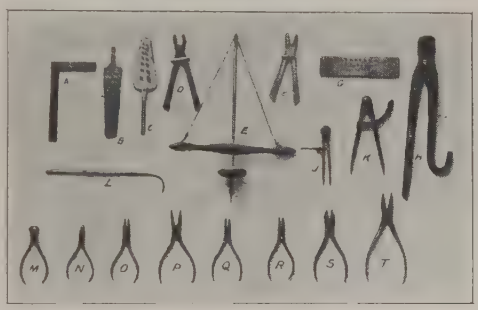
PORTION OF ENGLISH WROUGHT-IRON SCREEN OF 1695 AT HAMPTON COURT PALACE

BRONZE GATES, BY ANTONIO GAI, IN FRONT OF THE LOGGIA OF THE CAMPANILE, VENICE

Considerations of Art in the Treatment of Metals. Embossing and Chasing. Casting, Spinning, and Turning. Engraving. Iron and Steel Work. Enamelling.

ART WORK IN METAL

THE work of the hand is the first and last consideration in the expression of art in metal-work of any kind. When such is adequately given, the result is always sufficient to justify its existence. There is no art in any piece of work which does not possess the qualities obtained by hand work. To demonstrate this it is only necessary to try to think of a machine producing a work of art. Such a thing is inconceivable, inasmuch as all art is the expression of man's thoughts and feelings. The hand well trained alone can achieve that. One of the most lamentable things is to witness the painful effort of a worker to imitate the result obtained by the use of machinery. In the ordinary workshop this seems to be the great desideratum—the essential. That it is necessary, then, to make art objects with the hands implies also that the design must be such as can best be expressed by hand work. Hence it follows that all designs should be made by one who not only knows the methods employed in the craft, but has also either practised it or is working in it. Not only so, but he must also have the keenest sympathy and enthusiasm for it. The designer and craftsman should be one and the same person, until he knows the craft so thoroughly that he can guide the work while being made by other hands than his own. For it is the artist who, by working continually in a chosen material, best understands its capabilities and what beauties can be wrested from it, as well as its limitations and suitable application. It is this true appreciation of the qualities of a particular metal which calls forth the highest design. To make the point clearer, attention is called to the frequent misapplication of metal-work, shown by the reproductions of woodwork, stone carving and plaster moulding, in wrought metal. This proceeds from a mistaken view of the use of metals, or the lack of either the knowledge of its capabilities or of invention and sympathy on the part of the designer. Not only is this true of the material, but also of the process, as in the case of wrought and cast work, where the difference should be felt and understood throughout the whole design.



1. VARIOUS TOOLS

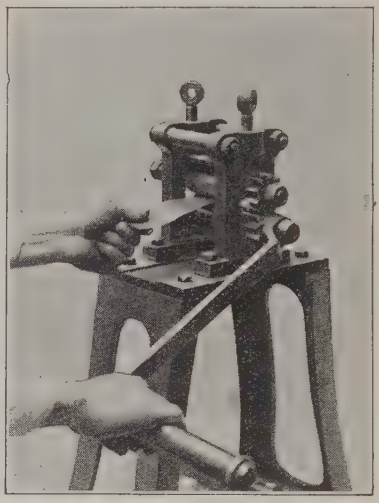
A. Steel straightedge *B* and *C*. Screw-plates *D* and *F*. Slide pliers *E*. Drill and stock *G*. Draw-plate *H*. Draw-tongs *J*. Spring dividers *K*. Wing compasses *L*. Mouth blowpipe *M*. Nippers *N* to *T*. Varieties of pliers

Study and Practice. The study and practice of the craft should be carried on at the same time as the study of design, either upon paper or in wax. They should not be pursued separately—that is, at different periods, one taken up for several years, and then the other—lest they both suffer. For by realising and embodying the idea or conception in metal, the mind gradually becomes accustomed to seeing clearly the design being made from start to finish in all its parts. In fact, so clearly is it perceived, that after a time the conception will present itself as vividly before the mind's eye as though it existed in actual metal before it. It is one of the most difficult mental problems to design or draw anything without having a clear presentiment or vision of the object. The usual method is to grope about over a piece of paper until something suggests itself from the number of lines sketched in, which, when it comes to be made, is found to look quite different from the drawing. Therefore it is best to advocate as a system of training the development of a constructive imagination, by the continual practice of both the design and the craft. They should never be regarded in the light of separate things. It is this unnatural divorce between craft and design which has been one of the chief causes of most of the deplorable work of the beginning and middle of the last century and much of the work of to-day. And one can only look forward to the time when they shall be united once more. Another deterrent in the production of art of a lofty aim is the lack of interest in fine art work of to-day displayed by the purchasing public. We are told that attention and devotion to ancient art is caused by the absence of really fine work to-day. At least, then, let us remove this cause.

Simplest Art is the Highest Art. Now, for reference only, the best study is to be found amongst the old work of the early periods of any civilisation. For specimens of goldsmithing and jewellery, those amongst the ancient Irish, Celtic, Greek, and what is left of Egyptian, Coptic and Scandinavian collections are to be sought; for wrought iron, British, German, Flemish, and French; for pewter, Dutch, English, and German; for silver, English, French, German, and Dutch; for enamels, French, German, and Italian. The earlier the date—in any civilisation of any piece of art work—the more generally does it imply the possession of those qualities which go to produce the finest art, such as simplicity, directness, purity of *motif*, restraint, virile strength, imagination and severity, together with the utmost perfection of handling and colour as seen in its best in the Irish jewellery. The later the period the more significant of redundance, femininity, extravagance, pretentiousness, poverty, and often impurity of *motif*—of conception, lack of breadth, simplicity, and the qualities possessed in earlier periods; such art work, so-called, has nothing but complete banality in all

its parts, as seen at its worst in the French and Flemish Rococo, and periods under the influence of the Jesuit Bourbons. The decadent periods are usually the precursors of social and artistic revolution. followed by a reaction affecting severity and simplicity, as seen in the Empire style of France and the Adams style in England.

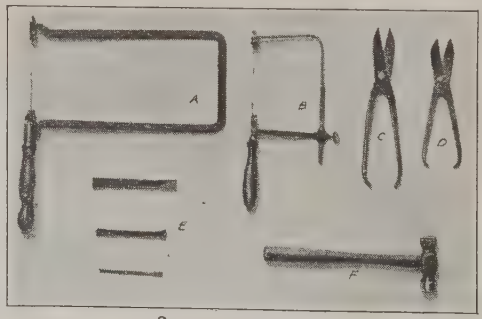
The True Value of Early Examples. The study of these styles or of any other should be for the sole purpose of understanding from them the expression of given forms and contours, contrasts and arrangements of line and mass not merely for the sake of the continuation and repetition of these styles, for no artist should be content to repeat the forms of expression used by men who have had their day and ceased to be. That is the wrong application of such study, and it is a sign of the times of how little is understood by the world of art when it is quite happy in seeing an endless purview of dead styles, thus causing on the part of artists and designers all effort of a sincere and original kind to be regarded as bad. This is prejudice and indifference, that kills or must be killed.



2. ROLLING METAL IN HAND MILL

This is a grotesque inversion of the idea held with regard to science and literature, and of what is considered advantageous and progressive for them. For in science the reverse holds good. In literature it would be considered as unworthy for authors to imitate the idioms, phraseology, and words as to repeat the ideas of writers in past times.

Study of Nature. Then, while studying ancient art, give more thought and reflection to Nature. Study her in all her varying moods, in her infinitely beautiful means of expression, from the smallest herb and flowering plant to the great trees, the movement expressed in their great limbs under the strain and stress of the storm, and the movement of the waters of the sea, and again the cloud masses. Then consider the lines expressive of calmness and strength in the steadfast hills; but study her most closely, intimately, in the forms and movements of animal life, and of the human figure. Do not study with the intention of copying, so much as to analyse what feeling or intention can be best expressed by adopting similar lines, masses, contours, whether of strength, beauty, grace, grandeur, gentleness; ascertain how she builds her forms and clothes them.



3. CUTTING TOOLS
A. Large frame and fret-saw *B*. Smaller ditto
C and *D*. Shears *E*. Chisels *F*. Hammer

Design. Referring in the most general terms to the broadest principles of design, it is necessary to bear in mind only that the straight line is the most beautiful of all lines, and that any deviation from it is less beautiful. Thus the curve, which is nearest the straight line, is the one that appeals to us most, as in early Egyptian, Greek, Celtic, and Saracenic art. So also in relief, flat surfaces are preferable to rounded, just as in the highest Greek form it is the flat planes and surfaces with the least curvature of parts which attain to that perfection of strength, beauty, and virility which one sees embodied there. Now, one of the great qualities in design is that described as "largeness of feeling." By analysis of most of those works which are generally conceded to be the finest, it will be noticed that this quality is maintained by simplicity, directness and singleness of conception, and scale in execution. It will be observed that there is a total absence of short curves, of violent light and shade, of prominent detail, and of confusion of parts, multiplicity of ideas, or complexity of aim. Detail, enrichment of surface, or ornament, elaboration of plan, were used so as to emphasise the beauty of the bare spaces, and in so doing these gave great preciousness to the enrichment. For it is apparent that straight lines, flat planes, simplicity of plan stand for and represent the great abstract quality *repose*, and therefore continuity, which implies infinity. In a similar way a curved line or surface repeated a great number of times suggests the same quality in a minor degree. If follows that all masses or curves, such as waves of the sea, or elaborations of whatever kind, carried on in a straight direction, repeated over a surface, represent the same idea. The trunk of a fir-tree, as straight as a column, or the slight curving growth of a chestnut, both indicate repose, because of the straightness of the direction of their growth. Contrast this with the gnarled oak. How eloquent it is of storms encountered and fought with! So that the broad principle is that continuity and simplicity, as represented by flatness of surface or straightness of direction, signify repose, infinity, and in the greatest work the sublime; and the contorted, twisted, intersecting, are emblematic of change. The smaller the curve and the more abrupt the angle of contour, the more rapid movement do they imply, and so on, in a descending scale.

Applying the Principles of Design. These general outlines the student must try to fill in for himself, and in doing so he will doubtless encounter many obstacles. But he will find ultimately that they are true. He will meet many things in nature, apart from the disputations of his fellows, which seem to say otherwise. It is important that

the student should understand the means of conveying his intention. If he wish to attempt to walk along the high and lonely road towards the lofty planes of the beautiful, he will find it necessary to exercise great restraint even while exercising his imagination to the full. He will find that the beautiful implies the abiding sense of continuity. Life itself is transitory in the individual, but continuous in the race. Reflect upon this, for it is generally understood that variety, change, and contrast are the most beautiful qualities in art, whereas the contrary is proved to be the case in all the greatest monuments of antiquity and the present day. Then, if in the greatest, surely in the humblest work also. To take but two of the best known examples of different styles, the Parthenon and the interior of Westminster Abbey. In the former the whole composition is made up of straight lines and flat planes. The interior at Westminster is similar in this respect where the shafts are simply a mass of upright columns tied together, which in their sustained length, gently and slowly curving at the top into arches, give the almost extreme perfection of the expression of aspiration in repose.

4. DRILLING WITH A DRILL IN A STOCK

Harmony in Art Work. Yet it is also one of the axioms of design that suitability of purpose should govern a building, and consequently the governing facts in its decoration should be that it is in harmony with that purpose. So that edifices of a serious great motive and intention shall be decorated only with suitable appropriate ornaments, just as much as those of a lighter character. These remarks seem to be so obviously true, and therefore unnecessary, yet how often does one see our theatres dull and heavy, our drawing-rooms uninspiring, our churches full of unsuitable crudities displaying the utmost poverty of imagination and inappropriateness of form and colour. All there is consists of only such ornaments as can be stolen from some historical document concerning the art of a period and religion of a character totally different from the present one; in fact, everything save that which should be in such places of worship, praise and prayer. The subject of design as applied to the right use of curves, accent, harmony, and other qualities, and the appropriate treatment of materials, are discussed in the article on Design.

5. SOLDERING WITH BLOWPIPE AND FOOT BELLOWS

Metals. The number of known metals is considerable, there being forty-five in all. The majority of these are suitable in one form or another for art metal work, although very few are employed to any great extent.

The following comparisons show the different properties and characters of metals, which are here arranged in the order of their suitability to the purpose named above them.

MALLEABILITY. Gold, silver, copper, tin, lead, brass, zinc, platinum, iron, aluminium.

DUCTILITY. Platinum, silver, iron, copper, gold, brass, aluminium, zinc, tin, lead.

FUSIBILITY. Aluminium, tin, lead, zinc, brass, bronze, silver, copper, gold, iron, platinum.

ALLOYS. Copper alloyed with zinc gives brass, copper alloyed with tin gives bronze, silver alloyed with copper gives standard silver, gold alloyed with silver and copper gives the different carats of gold.

The junction of metals is attained by various means as follows:

In gold work the parts are joined by solder made of gold and silver or gold, silver, and copper melted together in proportions according to the carat of the gold.

In silver work a solder is also used made of silver and copper.

In copper work spelter made of copper and zinc, and a solder of copper and silver in much the same proportion.

In brass work spelter and a common silver solder, made of brass and silver is used.

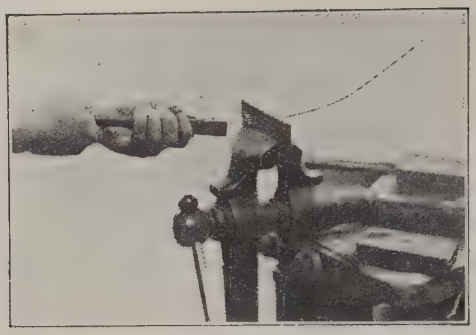
In iron work by welding and brazing.

In pewter, lead and tin and aluminium by fusion, and by pewter solder.

Nickel by silver solder.

All metals can be screwed, tied or riveted together.

That metals differ very widely in many respects, and that they are hard and soft and of different colour, is common knowledge. These differences can be modified considerably in most cases, which enables the worker to produce many things which otherwise would be impossible. Steel is the hardest metal. It is made from iron by introducing carbon into it while in a molten condition. But it can be made into a soft, pliable, or rigid metal according to the different properties of carbon and iron, or as brittle as glass by different applications of heat and methods of cooling afterwards. Possessing this remarkable quality it has become the most useful of all metals. Copper is the next most useful metal. Tin, lead, and zinc are largely used when mixed with other metals or applied to them. Gold and silver, besides being the most beautiful, are among the rarest metals found in the earth, and this prohibits them from being more generally employed. Other metals such as cadmium, vanadium,



6. DRAWING WIRE

palladium, nickel, mercury are untarnishable metals of a silvery quality, which are usually applied to other metals for their reflective qualities, and for the protection of others the surfaces of which would otherwise rapidly deteriorate through chemical change caused by the atmosphere.

Processes in Metal-work. In the manipulation of all metals, the same processes are employed. The main difference in treatment lies in the size of work and the quality of handling. In the precious metals, gold, silver, and platinum, the handling should be kept fine and delicate according to the size and preciousness of the material—consequently the tools [1] are small and minute, whereas in making wrought iron they are, comparatively speaking, of enormous size. The hammers and punches, the drills and stocks, the stakes, mandrels and files are naturally regulated by the size of the work. So that here we shall describe the processes in detail common to all, in reading which it will be necessary for the student only to think of his material—either copper, iron, steel, gold or silver—to understand the matter rightly. All metals can now be procured in the sheet, bar, rod, or wire of almost any dimensions. Most of these are prepared by machinery to-day, and are as perfect as is necessary for all intents and purposes. The method employed in making sheet metals is as follows :

An ingot of the metal is cast measuring and weighing the proportionate amount to the sheet required. This is hammered into a flat piece, and after annealing it is placed between the steel rollers of the rolling or flatting mills [2], and then rolled, the size being gradually reduced by the tightening of the rollers to the gauge decided upon.

The gauge is a flat piece of steel about $\frac{1}{8}$ in. thick, and having along both its edges a series of slots with a number marked below each for the purpose of quotations and reference, as seen in the illustration. There are two gauges in general use in this country, which causes great inconvenience owing to the frequent misunderstanding of the numbers quoted, so that it is highly necessary to state the kind of gauge which is referred to in an order. The names of these gauges are "Metal Gauge" and "Birmingham Wire Gauge."

7. "BLOCKING OUT" A BOWL

Sheet Metal. "Sheet" iron, copper, brass, gilding metal, are sold in sheets of varying dimensions, the most general size being about 4 ft. by 2 ft. The limit is according to the size of the rolling mills. To Mr. Sherard Cowper Coles we are indebted for an improvement in this limitation of size as regards copper inasmuch as by electrically depositing copper upon a cylinder a much greater size is reached and greater saving in the cost of production.

Annealing. Annealing is a word used to denote the process by which a metal is softened to its normal state after it becomes hard through bending, torsion, hammering, rolling, or through any process which involves the pressure of the particles of metal upon each other. Fine gold, fine silver, lead and tin do not become hard by hammering, but alloyed gold and silver, nevertheless, become hard enough to require annealing. Each metal requiring annealing is subject to the following treatment. It is first made hot, and kept hot equally all over, if possible, for a few minutes, and then allowed to cool gradually. In the case of steel it is necessary to arrange so that it cools very slowly, protecting it from the air while so doing. Other metals do not require so much care, but brass, low carat gold and standard silver should never be cooled rapidly by plunging into cold water, as may be done with copper.

Cutting. For all the soft metals—gold, silver, copper, tin, lead, nickel, iron and brass—if of an ordinary thickness a pair of steel shears or cutting pliers, or a metal-saw or fret-saw [3] is used for cutting. Shears can be bought either curved or straight, and suitable for cutting with the left hand or right. Metal-saws of almost any size can also be readily obtained. For cutting hard metals or thick metals, steel chisels are used. The angle at which these are sharpened is a very wide one, in order to keep the strength well down to its cutting edge, and they are tempered to a straw colour. Fret-sawing is done by first drilling holes in the various parts to be cut out, and then passing the saw through, fixing it firmly in the frame, and sawing in the usual manner, keeping the saw at right angles to the sheet of metal.

Tempering. Although tempering belongs particularly to one metal only, yet, as it has to do entirely with tools, we must describe it here. The first thing in making a steel tool is to soften the steel by heating it to a pale red and allowing it to cool very gradually, and then, when cold, to file it into the desired shape if a straight tool, such as a chisel, and if for a curved tool, by bending it while red hot. Then, to temper it, the steel is hardened by heating it again to a pale, red colour and plunging it into cold water. After this, one side is cleaned by emery cloth, and then a blowpipe flame is applied to within an inch or half an inch, as the case may be, until this part appears blue and the tip an orange colour. The moment this is reached the tool is plunged once more into cold water to arrest its further progress of softening. Now the tool is hard where it is straw colour, but not brittle, and tough where it is blue, yet not soft enough to bend while being struck. Swords are tempered in the same way.

Drilling. In order to fix some parts of metal work together it frequently happens that they cannot be brazed, soldered, or welded together. In such cases the parts are held together by rivets or screws. Before any of these operations can be performed the separate pieces must be drilled [**4**]. Now, drilling is done either by means of a drill rotated by a bow, or fixed in a stock, or by a chuck placed in a lathe. A complete set of drills can be obtained from any silver or copper warehouse. The whole operation of drilling is a very simple one, as it entails merely the fixing of the drill securely into the breastplate if a bow is used, or into the stock or chuck, and causing it to revolve rapidly upon a given point. Drilling is aided by the addition of a little oil placed at the point of the drill for soft metals, and of soapy water for steel

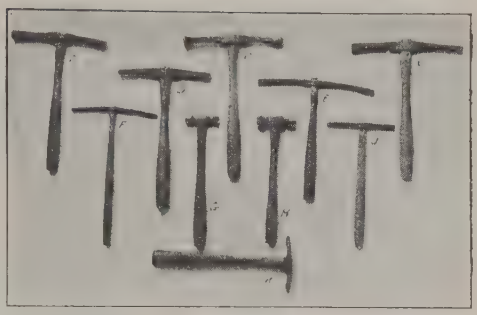
Soldering and Brazing. Soldering and brazing are identical in their process, which is performed as follows: The two surfaces are cleaned thoroughly either by filing or scraping or rubbing with emery paper, and when these parts are thoroughly clean the pieces of the metal are bound together with wire or held in position by clamps, or are fixed in fireclay or upon other stouter pieces of metal, and then the parts to be soldered or brazed are painted with borax dissolved in water, and the

9. PLANISHING A SILVER BOWL ON A STEEL-FACED STAKE

solder is cut into small pieces, which are placed along the boraxed parts. When this has been done the whole is subjected to a red heat produced by a gas blowpipe [**5**]. In the case of small work, such as jewellery, a mouth blowpipe is preferable; but for large work a large blowpipe with a foot bellows is used.

Wire-drawing. The process of wire-drawing [**6**] is performed by means of pulling the wire through a regular series of holes pierced in a hard steel-plate by tongs. This plate is called a *draw-plate* and the tongs *draw-tongs*. As the metal wire becomes very hard and brittle in the process of drawing, it is necessary to anneal it repeatedly and to use a little oil when passing it through the plate.

Hammering. The methods employed are practically the same as have existed from antiquity. They consist of first raising the metal from the back and then finishing it from the front. The softer metals only are used for the purpose of making objects such as cups, tazzas, bowls, vases and other articles of a similar form. The tools employed are those of the most primitive yet effectual character. They are hammers of various kinds [**8**], as shown in the illustration, the size of which is naturally governed by the size of the object. The long-headed hammers are used for raising and drawing in the



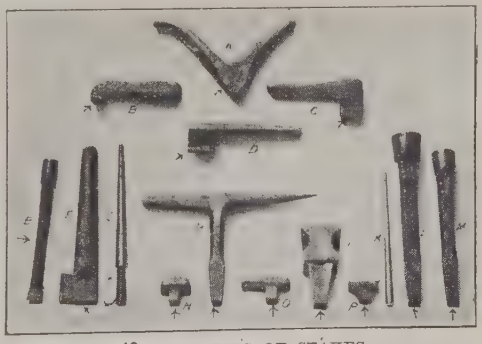
8. HAMMERS FOR ART METAL WORKERS
G and *H* are planishing hammers; the remainder are for raising, "blocking out" and "drawing in"

metal, and the short, flat ones for finishing and planishing, as it is called, with stakes, mandrels, angle wires, tee-pieces, and the like.

The detailed process of raising and drawing of a silver bowl, such as the one in the illustration, is as follows:

Cut your piece of metal from a flat sheet No. 18 metal gauge. Measure the edge of the design from the centre of the base of the bowl to its edge, and allow a quarter of an inch for cutting and filing this true at the end of the operation. Then strike out on your silver a circle, with this as the radius, with a pair of steel dividers. When this is done cut it out with a pair of shears, and then place it upon a block of wood, similar to that used by a butcher; with a hammer made of buffalo horn strike it in a series of circles, with regular blows, holding the silver at an angle of about 25° to the block [**7**]. It is better if the block is slightly concave. Then anneal it. After it is cool, take the silver again, and by holding at an angle of 30°, repeat the process of hammering again; and so on, until it is raised into a shallow saucer. After it has been annealed and pickled, turn it over on to a stake of this shape, and strike it on the outside in a similar way [**9**], turning it slowly with the left hand as you hammer it.

The important thing to aim at is to direct each blow upon the part which is immediately in contact with the stake; each blow should produce a clear, sharp, metallic ring, and in this way the silver is stretched into the shape of the stake, which should, of course, be the shape of the cup at some part or another. From this it will be gathered that the



10. VARIETIES OF STAKES
A to *D*. Side stakes *E*. Canister stake *F*. Side stake *G*. Ring mandrel *H*. Beck iron *J*. Square-faced stake *K*. Ringed stake *L* and *M*. Canister stakes *N* to *P*. Heads for vice crank

stakes required [10] are considerable in number, as it is obvious that each section of a given bowl should have its corresponding stake upon which the metal can be beaten into shape. When each complete course of hammering has taken place, the silver must be annealed and carefully cleaned. Then the operation of planishing completes the process. It is exactly the same as other hammering, except that it is performed by a short, flat-headed hammer, with a polished face. From its lowest part up to the rim the cup is slowly and thoroughly beaten with it until all other hammer marks are erased, and a regular faceting of the surface has been given to it. If it is perfectly done it should not require to be polished afterwards.

The above description will apply equally to the raising of any forms in any metals. Such metals as nickel and steel are naturally unsuitable for this work, as they are too hard.

Embossing, Repoussé, Chasing. *Embossing* and *chasing* are terms applied to the methods of enriching an object in metals by relief, produced through beating it with punches which are struck by a hammer first from the back to raise parts and then from the front to sink others, and to finish the raised parts.

The simplest form of embossing is done upon a lead block, and for large, simple decorative wrought work it is quite sufficient. But the finer kinds of "repoussé" or "embossed" work [11] are done upon a composition of pitch, plaster and oil. The great drawback to this composition is the amount of time taken up in fixing the plate to the pitch, and taking it off and re-cleaning it. But there is no other composition half so good. The tools are made from square steel rods, which are cut into lengths of 6 in. or 7 in. each, shaped at the ends according to the required line or relief. They are entirely dependent upon this and the size of the curves, or parts in relief for their shape. They are tempered straw colour at their ends. The number of tools of this kind that a chaser possesses is, as a rule, very great. As many as 150 are often required if the chaser does a great variety of work. Then he has small riffles, which are pieces of steel having at each end a little curved or flat tong of a file, either coarsely or finely grained. It is a method of work which is capable of giving great beauty and richness to metal surfaces.

After the design has been drawn or transferred to the back of a sheet of metal it is traced—that is, gone over with a flat blunt chisel-shaped tool, which is struck regularly with a chaser's hammer while the tool moves slowly along the line. The parts which are to be raised are forced up in the same manner with larger, rounder faced tools of the same convexity as that part of the relief. This is repeated, using different suitable tools until the whole presents from the other side a roughly-embossed relief. After it has been removed from the pitch and cleaned, the back now requires to be filled with pitch and placed upon a pitch block, or bowl, as the case may be. And the surface is improved by the gradual smoothing and finishing with punches. Here parts are made sharper and clearer, and there more soft and delicate. In **12** and **13** are illustrated some early specimens of art metal produced by these processes.

11. METAL REPOUSSÉ SHRINE OF FOURTEENTH CENTURY WORKMANSHIP

Casting. The central principle of casting, of which an example is shown in **15**, consists in making a mould and then pouring metal into it, or depositing by electricity. There are three ways of doing this, properly speaking—by sand, by "lost wax" ("cire perdu" or "cera perduta") or by electrolytic deposition.

The first is carried out by making a piece mould in wet sand from a plaster of wax model, and then the parts are firmly placed together in an iron box. The whole sand mould is dried, and the metal, while in a liquid state, is poured into it.

The *cire perdu, cera perduta*, or lost wax method, differs widely from the above. It is briefly performed as follows: After a plaster mould has been taken of the original model in beeswax, with the least amount of rape oil added to soften it, together with a little colouring matter, it is pressed into it, thus giving a model in pure wax. A core is inserted of brickdust and plaster, and on the outside a very solid mass of the same composition is put. Upon the model rods of wax are set on its prominent parts, passing up through the outer mould. After the whole mass has been subjected to a continuous regular heat for some time, during which the mould has been drying and the wax running out, the metal is poured into the main duct, from which it is carried through the other ducts on to the mould. By this means the whole thing is practically reproduced as in the original, as the metal now occupies the exact position of the wax, as though the wax had been transformed to metal. Further details of casting will be found in the section on Sculpture.

Electric deposition is simply the deposition of copper or silver or gold into a gutta-percha or vulcanite mould, which is immersed in a bath of solution of sulphate of copper.

Spinning and Turning. Two modern methods, which are closely allied in their processes, are spinning and turning. They are mechanical methods, and are to be decried for many reasons, the most important of which is given at the beginning of the introduction. Yet it is necessary and advantageous to know how to accomplish a piece of true spinning and turning—for this reason, that there are frequently parts of an object in metal which have to be exactly fitting and corresponding to other parts in their construction, so that they cannot be so well or quickly done by any other means. Examples of the method of making

12. CUPS AND GOBLETS OF THE SIXTEENTH AND SEVENTEENTH CENTURIES

various objects will be illustrated and described in detail.

Spinning is a method which achieves the same result upon a piece of sheet metal as is produced by hammering. The manner in which this is performed by hand without the aid of power is as follows. First a shape, in its simplest contour, resembling that of the bowl, cup, or other object, is turned in a hard wood, such as box, beechwood, or mahogany. Upon this the metal is securely fixed, with its centre placed exactly against the back-centre of the lathe. Then the "chuck," as the wood shape is termed, is revolved, carrying with it the metal disc, and while revolving, the end of the long steel burnisher is pressed with considerable force against the chuck, the handle forced underneath the armpit, and the middle of the tool supported on the slide rest, so that the whole weight of the body can be used. This is aided either by the lathe being placed as near to a wall as would allow a man to put his back against, or a leather strap fastened to the lathe, which goes round his back, thus enabling him to push with great force the burnisher upon the metal, and so press it down upon the wooden shape. When the first shape has been reached, the metal is annealed and the wood is taken a further stage. Then the metal is turned a little more into the shape desired. The metal is then again fixed against the wood, and the process repeated until the object is finished.

13. EARLY ICELANDIC CHALICE OF SILVER PARCEL-GILT

Turning in metal is similar to any other turning. Sharp-edged, chisel-shaped tools are employed, such as are shown in **14**, while the metal, solid, or hollow, or held securely upon a wooden shape, is revolved upon the chuck. These tools cut into the metal, giving the required form. All the tools mentioned are, with the exception of the lathe, of the simplest possible description. There are in large workshops innumerable varieties of most of these, but they are generally such as are for large work and thick metal. They are time-saving machines where a number of men are employed, but are too costly for small workshops. The lathe, however, is almost a necessity, for with it many things can be done with ease which otherwise would waste the time of the artist craftsman.

The most suitable metals for spinning are gold, copper, silver, brass, and pewter; and for turning, brass, silver, and copper.

Acids. The acids which are used in metal-work and enamelling are sulphuric, nitric, hydrochloric, muriatic, hydrofluoric. They are employed for different purposes.

Sulphuric acid, mixed with water in the proportion of 1 part of acid to 20 parts of water, is the most useful for cleaning copper, silver, and gold, both before and after soldering. It cleans the metal

in both cases, so that in the first place the solder runs smoothly, and afterwards it dissolves the borax. It is most advantageously used when heated to boiling point. The first operation in cleaning metal—that is, of leaving the metal in cold sulphuric acid and water—is called *pickling;* the second is generally referred to as *boiling out.*

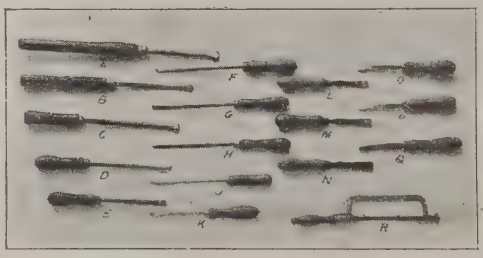
Nitric acid, or *aqua fortis,* is used in the process called *dipping* copper or brass objects. That is, after a piece of copper or brass has been cleaned in *pickle,* otherwise sulphuric acid and water, it is held on a copper wire and dipped into a bath of aqua fortis, which is commercial nitric acid. For most dipping it is sufficient to use it below the pure state. Dipping is a term given to the process of sudden immersion and removal from the bath, by which a brilliant surface is given to the metal.

Hydrochloric, or aqueous sulphuric acid, is sometimes preferred by goldsmiths for cleaning gold and giving it a yellow colour, as it dissolves the alloy of copper. It is also occasionally used in cleaning copper, particularly when it is to be electro-gilded afterwards. The most general use to which it is put is in what is termed "soft soldering," that is, soldering with pewter solder. For this purpose the acid—or, as it is popularly called, *spirits of salt*—is killed by dropping particles of zinc into the acid, which is then put upon the parts to be soldered.

Aqua regia is a mixture of hydrochloric and nitric acid.

Muriatic acid is largely used in colouring gold articles.

Hydrofluoric acid attacks any kind of enamel or glass. It decomposes the silicates, which are the chief parts of glass. For the purpose of removing any portion of the surface of enamel, or for dissolving it entirely, this acid is the only one which can be employed. It is a very dangerous acid, and should be used with great care.



14. VARIOUS TOOLS
A to *E.* Tools for spinning *F* to *K.* Turning tools
L to *Q.* Screw-cutting tools *R.* Hack-saw

Polishing. If a surface of metal be rough through filing, the method of smoothing and polishing by hand is as follows. Take rough emery cloth and rub it all over until the file marks are removed; then use a finer emery cloth, in grades, until the finest is used. After this, take powdered pumice and oil, and with a stiff brush scrub it all over until a smooth surface is obtained. Then, with a soft woollen or worsted material and rottenstone mixed with oil, rub it again, when a dull polish will be given. Then, with a chamois leather and rouge polish it brightly. To polish in a lathe the same means are employed, save that mops, buffs, and laps are employed, fixed on the chuck.

Burnishing. By the use of a burnisher, either of steel, hematite, or agate, a still higher degree of polish can be obtained. Burnishers are made in all kinds of shapes to meet the requirements of the article to be burnished, and are used with a little soapy water. Continual light rubbing in various directions, while the object is held rigidly in a piece of fine tissue paper or chamois leather, produces a brilliant burnished surface.

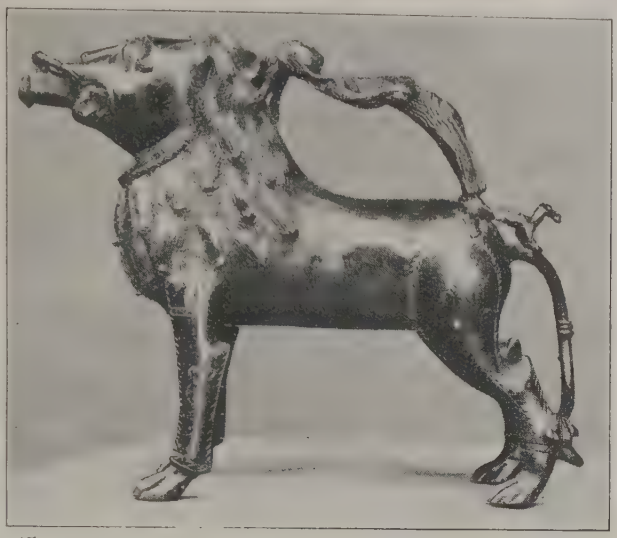
Engraving. Properly speaking, this art is the oldest of all known methods of enriching metallic surfaces, as it is found in the earliest periods of the Bronze Age. For with a pointed instrument made of hard stone, such as a flint, it was found that a line could be scratched or cut in the metal. From this to the exquisitely engraved work of the Irish Celtic jewellery [16], and later of the fifteenth and sixteenth centuries, is, after all, a small step in result, yet it took ages in its achievement. The great obstacle in the development was the tardiness with which the discovery of steel was made. From the smelting of bronze to that of iron whole periods of the struggle for existence and for man's development passed away. Then, from the forging of iron to its conversion into steel, even in the most primitive form, necessitated long stretches of time in human advancement. The conquest of material and the subjugation of natural forces to man's will is a slow one, even when, as now, the greatest talent is devoted exclusively to that particular direction and aim. When the mind has been taught to rely upon itself for aid, and has been slowly but laboriously disencumbered of all the wild phantasmagoria inherent to the savage man-child, we come to the development when we can go out and obtain in the simplest fashion the steel graver of to-day.

Engraving Tools. Yet no discovery which simplifies things for the many is entirely without its drawbacks for the individual. The tools which, as in this case, are to be used directly by the hand must be such as will suit the hand of the operator using them. Therefore, when you have purchased them, the first thing you will find is that it is necessary to shorten the tools and cut the handle to the shape of your own particular hand. Many engravers find it advantageous to employ a long handle with a small, roundish head that will fit into the palm of the hand. Others prefer a short handle. Again, most of the tools, gravers, spitzsticklers, scorpers, etc., are cut at a too oblique angle for metal engraving—which causes the edge to be liable to break. The first thing to do, then, is to make the tool and handle fit your own hands. If you find it advantageous to shorten the tool, you must first of all soften the steel by heating it to a pale red, and then allow it to cool, after which you file it down, smooth it up with emery cloth, and then temper it as already described. Then sharpen upon an oilstone (fine Turkey stone is the best, and should always be kept clean and covered, to protect it from dust). In sharpening, take care not to cut the stone into grooves, or you will spoil it, and it will be of no further use.

The next thing to do is to fasten your plate, or cup, or whatever the object is, firmly upon a stick or block, as the case may be. For small work, such as a ring or pendant, place some melted resin on the end of a round stick, then warm the resin, and fasten the article to it. If, on the other hand, the object is a cup or large object, fill it with pitch and put it upon a pitch block as though for chasing. Then hold the arm rigidly, the thumb pressed firmly against the plate, and by pressing with the back of the hand forward and rotating the stick —or block—in a contrary direction as the design may require, the line will be cut. It is obvious that the tool must cut along laterally, and not in a

downward direction, and it is by constant practice that this is acquired. The line is then cut deeper and broader, according to the boldness or delicacy desired.

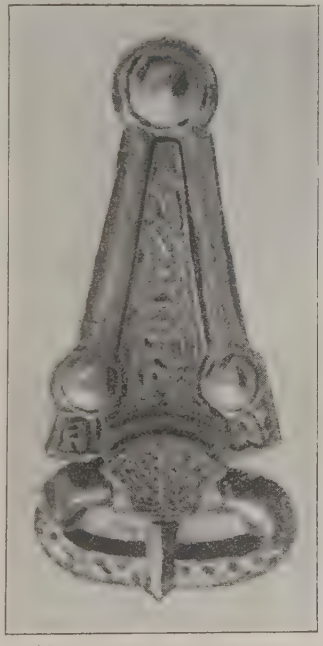
For different effects the line is cut hollow, curved, V-shaped, or flat; for each of these the tool must be accurately made. It is a good thing to practise cutting all sorts of curves by different gravers and to compare the result, and then to examine the best work through the knowledge thus obtained. For damascening, niello, and enamelling the same process is employed, with this sole difference—that the parts in which the gold or silver is to be let in the steel, as in damascening—or the sulphide of silver and lead to be melted in as in niello, or the enamel fused in the spaces cut out as in champlevé enamelling—are cut much deeper than is the case for engraving simply. These latter processes will be described under their proper headings.



15. FLEMISH CAST, BRASS EWER OF FOURTEENTH CENTURY

Engraving on a small scale, either for gold, silver, copper, brass, or iron, is invariably done by the unaided pressure of the hand holding the graver. But for large work, such as memorial brasses for inscriptions, hammer and chisels are used. In this case the chisel is held in the left hand and struck with a chaser's hammer, much in the same way that repoussé tools are used, save that, instead of beating the chisel while holding it at right angles to the surface of the metal as in repoussé, the chisel is held obliquely at about an angle of 45°. Little pieces are flaked off at about every third blow. Another method is properly described as etching, but it is often erroneously referred to as engraving by acid, and does not come into this category.

Die-sinking. Die-sinking is very intimately connected with engraving and carving. Carving is very rarely done, as metal does not yield to such treatment as well as to other methods described. But die-sinking is one of the most common of the operations to which metals are subject, and it is at the same time a distinct method, so that it requires adequate description. It is generally used in striking medals, coins, badges, or other articles in bronze, copper, silver, or gold, in which fine detail is required, and where the work is to be reproduced many times. A block of steel is used. It measures across the face a little more than the piece to be struck, and deep according to the size of this face, in order to withstand enormous pressure. Then, upon this prepared surface—that is, a perfectly true smooth surface—a mould is carved with steel chisels, gravers, and riffles. A very careful model is made in plaster, and is then copied in the steel. It is a work which requires the greatest knowledge of the use of tools, as well as the most careful, concentrated effort. A really fine knowledge of form and modelling is absolutely necessary. While the process of carving or die-sinking is in progress, wax impressions must be repeatedly taken in order to see how the work is going on. When it is complete, the surface must be tempered, and, upon this being satisfactorily accomplished, the die is placed in a press, or underneath a heavy bolt, raised by a pulley and dropped, and the metal disc is struck. If the die is not properly annealed and tempered it will crack in this process. The metal disc also must be of the softest description and carefully annealed.



16. SILVER-GILT FILIGREE BUCKLE

Niello. Niello is an inlay of an amalgam of silver, lead, and copper, in the proportion of 12 parts of silver, two parts of copper, and one of lead, to which is added powdered sulphur in excess while the mixture is in a fluid state in the crucible. This is pulverised when cold, and into the engraved parts of silver, gold, or copper the powder is placed. But before doing this it is necessary to apply a little borax, and run it well on to the engraved parts, then the powdered amalgam is shaken all over the metal thickly and baked. After it is withdrawn and the defective parts mended, the whole is rubbed down with files and emery, and finally polished. It was at one time very largely used upon silver. A considerable amount is still done in Italy and Spain, but it has never been very much in request in England, probably owing to its absence of colour. The great examples are the altar frontals at Pistoria Cathedral and at the baptistery at Florence.

Goldsmith's Work. The jewel in the illustration [19] is built up of separate parts. First the vase shape is made by beating out a strip of metal the length of the circumference, and then the part immediately above it, first as a cone, the lower edge of which is spread out on a mandrel; then the base is beaten out of a small circular disc, in a saucer shape, and these pieces are soldered together. The granular surface is obtained by soldering grains of gold upon this. The simplest method of making these is to cut up minute pieces of gold wire of exactly the same length, and melt them on a charcoal block, pressing the pieces into the charcoal. Then, after picking them out of the charcoal, they are shaken together in a bag, and afterwards rolled gently and evenly by hand between two true flat steel plates. By this means the grains will become spherical. A little calcined borax is mixed upon a slate, with water and gold solder filings added; a paste of this is made, and put on the gold. Now, with a mouth blowpipe, this is melted all over the surface. When this has been done, and it is quite cool, the grains are placed regularly upon the surface, and with a little gum tragacanth they are fixed. Then the flame of the blowpipe is blown gently upon them, drying the gum, and taking it up gradually to a red heat, so that the solder just melts, and causes the grains to adhere to the surface.

17. GOLD ARMLET

Many of the Etruscan jewels, such as that shown in **20**, were enriched in this manner. The making of the filigree is of the simplest description. Take a small wire, flatten it with a small hammer, and bend it round with round-nosed pliers. Then tie it in position with fine iron binding wire, and solder it to the main piece in the manner already described.

The armlet illustrated in **17** could be quickly and efficiently made by hammering the cylindrical shape in two halves from a piece of fine gold, of No. 10 metal gauge, by soldering them together, and then by cutting out the bird form in a thick piece of gold and soldering it with 20-carat gold solder. The head, horns, and paws are also made out of thick sheet metal and soldered to the body. Then the settings for the stones, which were in the body, are soldered on also. The probable way in which this was made was by modelling in wax in a cone, and casting, and afterwards chasing. This method is a good one, and is the best, as well as the simplest, but the cost of the solid gold would naturally be very considerable.

Silversmithing. The cup shown in **24**, of which the author once made a replica, is one of the most highly admired objects in the South Kensington Museum. It is of silver-gilt, and round the cup and cover it has pieces of green enamel *plique à jour*. It is not so much an elaborate work of art as a perfect piece of refined taste and craftsmanship. The principal excellence is the exquisite finish and proportion. The mode of its manufacture is as follows.

The body of the cup is hammered out of a sheet of silver, as described briefly in the general remarks under Hammering. A circular piece of sheet metal, of No. 18 metal gauge, is cut out with shears. The width of the base is struck out with compasses, and then, upon a wooden block, the metal is beaten into a series of rings, the metal being held at an angle of about 30° to the block, and, after annealing, the operation is repeated at a greater angle, and so on. Then it is turned over on to a stake and beaten from the outside, and thus drawn in. Finally, it is planished and polished. Now upon this is marked out the exact position of the mounts to hold the enamel. These mounts, made from a thick piece of wire, are chased and drawn by hammering, chiselling, and filing. Then the enamels are made as described under Plique à Jour. Now cut out the spaces, and upon the body pounce with a sharp graver the pattern. After it has been gilt, the enamels are fixed. A more ornate sample of the same class of work is shown in **18**.

Wrought Iron and Steel. From the fashioning of armour plate, the forging of a damascened and jewelled Toledo blade, to the humble smithing of a horseshoe, from the making of an anchor to a grille or lock-plate, forms a fascinating study of work in iron and steel. Of late years, the smithing of iron has become one of the finest crafts.

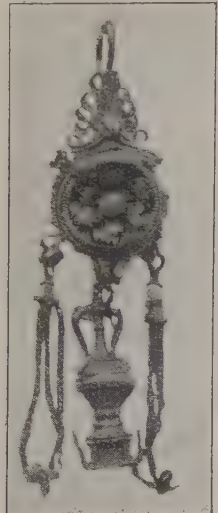
In ancient times, when all objects of utility, as well as of adornment, were marked with a desire for beauty, when the most frequently used kitchen meat-jack was regarded not only as a thing of use, but also as something that might be made beautiful, iron-work flourished in all its excellence. Contrast the iron-work of from 50 to 100 years ago, when it was deemed sufficient if it served its purpose and nothing more, with such work of ancient times—with the hinges illustrated in **21**. Why is it that a piece of engineering work is generally ugly? It

should be that the tool, or structure, which serves its purpose of utility best should also be the most beautiful, for beauty depends more upon the fitness of intention to purpose than upon anything else, and any extraneous adornment or unsuitability, or unnecessary feature, should signify a defect in design. And so it does. For, rightly considered, it is always the beginning, and therefore imperfect engineering or mechanical inventions which are ugly, and as they grow to perfection as things of utility they become less ugly.

Iron and steel are the most useful of all metals, but most of the ironwork, engineering or otherwise, which one sees is not beautiful, principally because it either fails in its purpose or does not completely fulfil it. The main characteristics which distinguish iron and steel from other metals are greater ductility, hardness, and infusibility. They oxidise more freely, and possess the property of becoming welded under pressure, produced generally by hammering when heated to a soft state. Steel, which is carbonised iron, differs from iron in that it is much harder and more brittle, but less malleable and ductile.

18. EARLY GERMAN CHRISMATORY

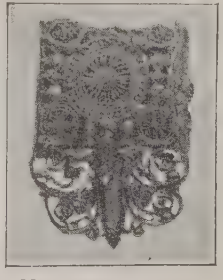
Varieties of Iron and Steel. There are substances lying intermediate between iron and steel; these are hard irons and soft steels, which depend upon the amount of carbon introduced into the iron. They are employed in a variety of ways. The most suitable iron for wrought purposes is almost pure iron, and contains but one-tenth per cent. of carbon. This will not harden under any circumstances, and welds readily. It is fibrous and tough. The greater the proportion of carbon in the composition of steel, the harder it is. It fuses at a lower temperature, it is granular, very tough, springy, and capable of being made soft, hard, or brittle. The very earliest forms of wrought iron show that the ore used was obtained from meteoric ore, as nickel is discovered in it when analysed, and there is a certainty that they were unable to smelt the ordinary ore. It was the custom, due to necessity, for the earliest workers in iron and steel to make all their own tools, and we know nothing which is better training than this. For to make a file, a pair of pliers, a repoussé tool, a mandrel and a graver, requires a great amount of knowledge and skill, and no doubt assisted the apprentice in obtaining a mastery over his material which, in most other ways, would be insufficiently acquired.



19. GREEK GOLD EARRING

In Theophilus' book we read of the method employed at that time in making steel and iron tools. The principal operation in wrought iron which distinguishes this work from all other kinds is that of welding. Welding consists in making two pieces of iron red hot, and consequently soft, and while in this condition, of hammering them together until they form one piece. It is the most complete union in all metalwork, for it is the absolute junction of two separate parts of the same material by itself; whereas, all other metals are joined by a solder of some kind. The most general methods of wrought-iron work are bending, chiselling, welding, riveting, and hammering.

Methods of Working Iron. Bending of thick iron is always done while the metal is red-hot, either upon a mandrel, in a vice, or upon an iron shape, and as it is heavy work, it is done by a man and his assistant. While one holds it securely with tongs or places it in a vice, the other beats it with a hammer, or twists it with other tongs. With leaf work, the iron is cut out from the sheet to a template, and is generally beaten into different shapes while cold, or if thick, while hot. Rods of all sizes, sheets of almost any thickness, strip of any gauge, can be readily procured from the metal merchant. In the forge, fine breeze is used, so that it falls closely round the iron. Small breeze burning is used with the bellows. It requires quick handling. In the making of any part, the best method of procedure is to make a pattern or template, on which the scroll or curve can be tested. In making thin work, it is scarcely necessary to heat at all, save for welding; but we deprecate very strongly the employment of thin iron out of doors, as in this climate it corrodes quickly. But a different set of tools and much greater skill is required



20. ANCIENT GREEK GOLD EARRING

21. MEDIÆVAL FRENCH CHEST HINGES

in dealing with thick iron. When using thick iron bar, the simplest way is to bend it by striking it over the anvil, or over shapes fixed in a vice. The anvil, owing to its tapering, circular, and flat ends, can be used for almost every variety of curve. The ease with which iron can be bent while red-hot is one of its sources of danger, inasmuch as it is apt to shrink, unless held firmly and beaten slowly. The geometrical volute in the scroll is never to be commended. It is one thing that the wrought-iron worker usually seeks to achieve, and it is a good thing to be able to do it easily, but only so that something better may be done in which the curve is one thought out and studied. As one walks along the street he notices that it is the most common form employed, and the result is dismal.

Cast Iron. The description of the method of casting in iron [22] will be given under Sand Casting. It is sufficient for our purpose to compare cast iron with wrought iron. Now, there is, so far as craftsmanship and treatment, no comparison in all such work as grilles, screens, and such places as require lightness in design. But where more massive work is required, such as newel posts to a gate, or large fire-dogs, or relief for the back of grate, then cast iron, suitably designed and handled, has its proper place. The work of Alfred Stevens in this material is, in some respect, the finest that has been done; but in spite of his great name, commend us to the work of some of the German and English cast-iron craftsmen of the early part of the fifteenth century. For iron suggests strength of a rude, simple kind; massive, blunt, heavy, solid, and full of power, not the polished, curving, adaptable, pliable, facile substance that copper or silver is. This remark applies largely to wrought iron as well as to the cast variety, for thin wrought-iron work is very unpleasant. We have frequently found wrought-iron railings with twisted scrolls and leaf work that you could break off with your fingers. Imagine what they will look like in a few years, when no amount of paint will hold them together. Again, one frequently sees parts which should have been welded held together by solder. Architects who pass such work are culpable through ignorance, indifference, or neglect.

22. CAST-IRON GONDOLA PROW, VENETIAN

Enamels and Enamelling. Enamels are composed of silica, minium, and potash fused together and combined, when in a state of fusion, with oxides of metals by which they obtain their colour. The chief oxides employed are those of cobalt, copper, iron, manganese, tin, and lead. Copper gives green, turquoise, and red. From iron, red, brown, and orange are obtained; manganese gives purple and cobalt blue. Tin and lead combined and calcined are used to make enamels opaque. All enamels are transparent before this calx—of lead and tin—are added. Chlorides of gold give ruby and silver yellow. These enamels are made in a crucible, and when properly run down into a clear vitreous mass are poured out into water. By doing this a great amount of time is saved in the subsequent operation of grinding, which is the next part of the process of enamelling.

23. PASTORAL STAFF, LIMOGES CHAMPLEVÉ ENAMEL

Enamelling is divided into five processes — namely, Champlevé, Cloisonné, Bassetaille, Plique à Jour, and Limoges, or painted enamels.

Champlevé Enamelling. Champlevé enamelling, of which a specimen is illustrated in 23, consists of two separate processes of engraving or carving and then filling these spaces in with enamel, and firing. A plate of copper, silver, or gold is taken and put upon pitch or resin attached to a bowl or stick (as described under Engraving), and the pattern sunk with a flat scorper to about one-sixteenth of an inch in depth, leaving the dividing outline of the pattern raised. Then the enamel is pulverised with a pestle and mortar in water until it is a fine powder. Now it is washed so that all the milky part is entirely removed, after which it is put into

a saucer, and with the aid of a spatula or a brush the sunk parts are filled up with the granulated enamel. It is now dried at the furnace, and when the furnace is of a pale red heat, it is slowly and carefully introduced, supported on a fireclay or iron planche. When it has become shiny it is withdrawn and allowed to cool. This is then examined, and if any parts are below the surface of the raised metal lines they are filled up again as before and fired once more. It is once more removed from the furnace and upon examination it will be found to have some parts raised beyond the others: these are ground down with a corundum file and water, and then refired.

24. BEAKER, WITH COVER, FIFTEENTH CENTURY

Cloisonné Enamelling. Cloisonné enamelling differs from the preceding only in the process of its preparation for the enamel. In this case the cloisons or flat, thin strips of metal, either gold, silver, or copper, are soldered to the metal surface to be enamelled. When the plate has been cleaned in "pickle" (sulphuric acid and water) the spaces are filled in as before and fired.

Bassetaille. This is a process in which the metal is carved in relief below the general surface of the surrounding metal. The metal is cut sharply with gravers and scorpers. It is most advisable first to make a careful model in wax, and then to copy it in the metal. Then fill in and fire. There are no metal divisions in this case, but by careful handling the edges will not mix, and they do not do so in the furnace unless greatly overheated.

Plique à Jour. Plique à jour is identical with cloisonné enamelling save that there is no background of metal to which the wires or cloisons are soldered. They are simply soldered to each other and between these spaces the enamel powder, mixed with gum tragacanth, is placed, dried carefully, and fired on a support which touches the edge of those parts where there is no enamel. This, for simple work, is very effective and easy. For more elaborate work such as a bowl or a cup, the metal cloison is laid upon a metal or fireclay base, which is filled in and fired as described for champlevé; and the base is afterwards removed either by acid or some other solvent.

25. ENAMELLING A PLATE ON WHICH THE SUBJECT HAS BEEN DRAWN IN IRIDIUM AND FIRED

Limoges or Painted Enamels. These enamels [26] are different in their manufacture from those obtained by the preceding processes. The sheet of metal is slightly domed so that it rests upon its edge. Underneath, it is covered with one coat of finely-ground enamel about one-eighth of an inch thick, and when this has been thoroughly dried it is turned over and the front is enamelled with a layer of rather coarsely ground enamels. The metal has, of course, been thoroughly cleaned as described under Pickling, before the enamel is spread upon it. This first layer is fixed and repaired, if necessary, until it is quite clean and bright. Then, upon this the subject or design is painted in white enamel, very finely ground with water, or with a glass muller upon a glass slab. With a brush it is then painted upon the prepared enamel plate [25]. A great degree of modulation can be given to this white by putting it on in varying thicknesses, and 27 is a good specimen of this. After firing, it is covered with transparent enamels and fired again.

Another most advantageous and peculiarly characteristic part of this process is the use of foil. Just as foil is used to heighten certain stones so it is used to heighten enamels. These paillons of foil are cut out and stuck upon the enamelled plate, after which the different coloured enamels are fused upon them. There is a great tendency to use foil, which should be guarded against as it is apt to give a meretricious effect.

The whole work is now taken in hand and parts are still further enriched with gold lines. The effect of a finely painted enamel is one of the most beautiful things it is possible to produce.

Sand Casting. Sand casting is generally employed where simple surfaces and planes are the dominating feature of the model. In preparing the model it is obviously necessary to bear in mind the process in which the work is to be carried out. For sand casting this should be arranged so that the mould in sand will draw easily in the fewest possible pieces. Sand casting is very largely the equivalent of plaster casting from a piece mould. In *cera perduta* the model may be of any shape, undercut, and of the most uneven and intricate

design. But the reverse holds good in sand casting. In modelling for small work such as jewellery, it is a great advantage to use rather a hard wax, which can be done with ease if it be warm, so that when it is cold it will set hard enough to press the mould from it. The larger the work the more desirable it is to have tools and appliances, but for jewellery the simplest mould in plaster and brickdust—or a sand mould—is sufficient.

The sand, which is finely prepared, is put into a box and pressed down in a wet state, until it is almost a solid mass. Upon this the impression of the mould is made. Then the reverse of the model is taken in the corresponding half of the box. A V-shaped hollow is cut from the inlet of the box on to the impressed mould and then the sand is dried. Charcoal powder is now sifted all over and the melted metal is poured into the mould from the crucible. This, in the simplest possible terms, is how sand casting is performed. From this groundwork the most elaborate system of casting has been built up. The elaborations consist in making the pieces, or piece moulds necessitated by the different planes of the model. If these are numerous, as in a group of figures, it naturally involves a great amount of careful planning and execution. All such pieces are united with iron or bronze pins, as the case may be, and the core or heart of the mould is fixed in position also with pins, in order to keep the inner edge of the mould and the outer surface of the core in their exactly separated positions; then the metal in a liquid state may run between them. Any parts of the mould, such as arms or legs of animals, or figures which are extended, are usually cut away from the main trunk and cast separately. They are joined afterwards by brazing or soldering and riveting—a process which simplifies the casting considerably. Most of the work which is not large in dimension and is composed of many surfaces is now cast in the lost wax, or *cire perdu*, process. To compare these processes would be invidious, for so much depends upon the skill of the artisan. But the above is a guide to their differences and advantages.

26. ENAMELLED PLATE IN VICTORIA AND ALBERT MUSEUM

27. PLAQUE OF COPPER PAINTED IN TRANSLUCENT ENAMEL COLOURS

General Considerations. It is hardly necessary to dwell further upon the various processes of metal-work or enamelling, or to elaborate in detail the intricate problems which present themselves in the practice of them. But it is as well to point out that the failures which everyone has to encounter at the beginning and during the pursuit of any art work, or, for that matter, any kind of work, and especially in its higher branches, wherein the element of chance so largely enters—such as in the case of repeatedly firing a piece of painted enamel—must all be considered as incidents by the way from which it is possible to derive valuable knowledge for future work. For the cause of each failure rightly accounted for and successfully overcome is a step on the ladder of achievement. Failures, then, should never be regarded in the light of discouragement and despair, but as obstacles in overcoming which increased knowledge and strength is gained.

It is most important also to bear in mind that the best results can be obtained only from a material by observing its properties and capabilities first, and never imposing conditions upon it which are foreign to its nature and composition, which will militate against success, but always endeavouring to express the true essentials of these properties. That is to say, the full appreciation of the fact that material (be it metal, enamel, or any other) which is taken up for the expression of an aesthetic emotion is in many respects both master and servant. By a rapid survey of work in which a misapplication of a material has been employed one can see what to avoid—such as in the case of mouldings, columns and capitals made in stone or wood which have been copied in metal, or, again, where the forms of natural flowers and leaves have been closely imitated, and made as though they were growing out of a wire on the side of cup.

Soil. Drainage. Manuring. Rotation of Crops. Seeds. Sowing. Transplanting. Hot and Cold Frames. The Common Vegetables. Monthly Programme. Choice of Seeds.

VEGETABLES & THEIR CULTIVATION

ANYONE who wishes to become a successful vegetable grower must watch carefully the progress of the infant plant, learn its habits, needs, likes, and dislikes, for only in this manner can he realise its possibilities, and thereby grow it to satisfaction. The germination of the seeds it is desired to sow must be studied; the suitability of the soil, climate, and aspect must also be considered. The markets that are available for the produce, and the class of vegetables most suitable for them, and whether there is sufficient local labour to attend to the harvesting of the crops, are all factors in the making or marring of the enterprise.

Very often there is a great waste of time, money, and labour, particularly with beginners, because they attempt too much, trying to grow too many different kinds of plants, when they would reap much better results financially by selecting only a few of the varieties that are most suitable for their particular conditions.

The wisest course is to grow the best of everything, and nothing but the best, and to leave severely alone anything of which the best cannot, owing to local or other conditions, be grown. The very first axiom to keep in mind with reference to land used for vegetable growing is that its productiveness must be strained to the utmost. No fallowing or resting of the ground must be allowed; it must always be under cultivation, one crop succeeding another in rapid succession; and if, as sometimes happens, the market is low and prices are bad for the particular vegetable that is ready, it should be dug into the soil, and it will pay well as a manure, this being particularly the case with such crops as cabbage, turnips, and greens. They should be buried in trenches, and other crops sown over them. It naturally follows that if a great deal is being taken off the ground in the way of crops, a great deal must be put back into the soil in the way of manure.

Selection of Soil. The selection of suitable soil for growing vegetables is of vital importance, and this fact cannot be too forcibly impressed upon the beginner. In some cases a piece of land that has been reclaimed will yield a good profit the first year, while in others, even after years of labour and the spending of large sums of money in manure and draining, the desired productiveness cannot be obtained. Many a man has made his initial mistake by the selection of an unsuitable soil.

Without question, the best soil for vegetable growing is one of an alluvial saline deposit, but this is very seldom found far from the sea. It consists of a dark, heavy loam, and can easily be told by the quantity of decomposed shells that will be found in it. Failing this, a somewhat lighter soil, from a foot to 18 in. deep, with a subsoil of yellow sandy soil, should be sought. Another good soil is one that is even lighter, the sand being in greater proportion than the loam, but this soil is almost useless for growing cabbages, celery, or onions. For those crops that are not required early, a soil that is known as clayey loam is best. It consists of a loamy soil with a percentage of clay in it about a foot in depth, and having a subsoil of stiff bluish clay, often spoken of as gault.

However, whatever the original state of the soil, whether of the garden or field, it will always admit of being brought to a greater state of fertility and productiveness. The soil, to be in first-rate condition—and this should be the aim of every serious grower—should be deep, rich, and moderately light, besides being well drained. Therefore, if the ground is wet, it must most certainly be drained.

Drainage. The systems and methods employed in the drainage of land naturally vary according to circumstances. For instance, a man may be a long way from any place where he can obtain tiles or clay pipes, whereas he may be able to obtain without any trouble creosoted boards or brushwood, and at a reasonable price [3]. Before starting any scheme of drainage it is necessary to find out the fall of the land—that is, the way the water naturally flows. A trench three or four feet deep has then to be dug across the field in the direction the water flows. In the bottom of this is placed a quantity of brushwood, medium-sized stones [2], flat stones, clay pipes, arched tiles, or wooden culvert, and the earth filled in again. If there is no outlet such as a ditch for the water to run into, a large pit must be dug that will form a pond by the water running out of the field into it.

Preparation of the Ground. The operation next in importance is that of aerating the soil—that is, allowing plenty of air to enter the earth, so that nutritious gases are assimilated, and food thus prepared for the plants that are to follow. This is accomplished by the process of what is termed *trenching*. The soil is removed to a depth of two or three spades, and into the trench thus made is thrown the top surface of rough, unbroken clods from the next strip or row that is to be dug, and the earth piled lightly up. With stiff, heavy land it is very important that it should be ridged before the winter, so as to expose as much of it as possible to the beneficial influence of frost which will crumble it up. At the same time, as the soil will be more or less broken and but lightly piled up, it will be in a better condition for the atmosphere to act upon it.

When preparing a large field for vegetables it will naturally be impossible to dig it all over by hand, and in these circumstances it should be subsoiled in the manner indicated in the chapter dealing with the preparation of the land for planting fruit trees. [See page 5060.]

The ground should always be thoroughly turned over two or three weeks before it is desired to use it for vegetables, that it may be sweet and loose to receive the plants or seeds. With heavy land it is also a very good plan to give liberal dressings of such materials as sand or road grit, cinder dust, or builders' rubbish, which will greatly help to lighten it up and make it work easier. When the land has been treated in this manner early in the winter, it will always be found profitable to spread over it a heavy application of stable manure.

With the approach of spring a coating of lime should be given, as most soils are deficient in this, and it should also be levelled. A trench should then be dug about 9 in. deep and about 6 in. wide, and the soil scattered on the land that is about to be dug over. Begin digging again at the end of the row, throwing the soil into the trench that has been made, taking care properly to bury the manure that has been lying on top of the ground all the winter, and any weeds that may happen to be about. All clods should be thoroughly pulverised and the surface made level.

Manuring. There is a great tendency on the part not only of amateurs but also of professionals to get all they can out of the land without putting much—if anything—back into it. This is undoubtedly an error of no mean importance. If more than those that have been receiving applications for several years. Clay lands and lands where a good deal of vegetable matter has been ploughed in will profit with a much heavier dressing than light soils, and it will be found that where lime is used liberally on stiff and heavy land the crops will be heavier, better, and earlier than previous ones.

Useful manures, other than stable and farmyard, are soot, carbon manure, fish and Canary guano, and the usual artificial manures.

Rotation of Crops. Nothing pays better than system in this industry, as in every other; it is therefore necessary that there should be a rotation of crops. By rotation is meant changing the crops, so that the same is not grown on the same piece of land two years in succession. It is better still to leave an interval of three or even four years.

	SECTION 1	SECTION 2	SECTION 3
	Time to Crop—Kind of Crop	*Time to Crop—Kind of Crop*	*Time to Crop—Kind of Crop*

1. DIAGRAM ILLUSTRATING THE ROTATION OF VEGETABLE CROPS

vegetable growing is to be made to pay, the very best vegetables must be grown, as there is ever plenty of second-rate stuff flooding the market. This production of the best cannot be accomplished without the aid of large quantities of manure. One of the most successful market-gardeners, and a man who has been in the business for over twenty years, uses from 50 to 100 tons of well-rotted manure per acre every year. The manure should be well rotted and thoroughly incorporated with the soil, otherwise injurious insects will breed in large numbers, and club and canker will do immense damage among the crops.

Lime is a very important factor in the production of garden crops; it sweetens and assists in pulverising the soil. The quantity to be applied per acre varies according to the soil, some land being far more deficient in it than others. Grass fields when first ploughed up naturally need a great deal

As an illustration of how this is arranged, suppose we take an acre of ground and divide it into three plots or sections, with a space of about 2 ft. between each section [1]. The whole of the land that is to be cultivated with vegetables can be treated in the same manner, whether it be a small kitchen garden or a 400-acre farm. Of course, in the latter case separate fields would be set aside for separate crops.

Having formed our sections or plots, the diagram will serve as a guide to the crops that should be grown on them. A path about 1 ft. wide should be left between each kind of crop, so that they can be properly cultivated without damage to plants growing by the side.

Storing Seed Potatoes. It is becoming more than ever the practice, before the winter, to place in shallow trays, like that shown in **13**, seed potatoes that are required for early sowing. They are kept in barns [**12**] or stores, stacked one on top of

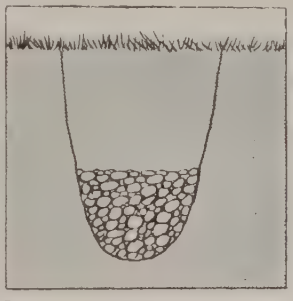
the other, with plenty of light ; and the temperature is kept above freezing-point by means of small oil-stoves. About once in three weeks the tiers of trays are taken down and restacked, placing the top trays at the bottom of the new tiers, so that the shoots are all strong and sturdy. If this is not done, it will be found that those in the bottom trays will have long, weakly, white shoots that will easily be broken off in planting.

By this method of boxing it is possible to plant them later, and so run less risk of their being cut off by frost. They will still be ready for market by the time those that have been sown earlier and not boxed are ready to be dug. Moreover, if the grower has a sheltered field, he can sow them at the same time as those that have not been boxed, and so have them ready for market much earlier.

The dimensions of these trays are 2 ft. 6 in. by 1 ft. 6 in., the sides and bottoms being made with $\frac{3}{8}$ in. wood ; the corner supports are made $1\frac{1}{4}$ in. square and 6 in. high, the sides are $3\frac{1}{2}$ in. high, and the handle $1\frac{1}{2}$ in. by $\frac{3}{4}$ in. A little space is left between each of the bottom boards to permit the air to circulate through.

As soon as these potatoes have been dug, the same ground should be immediately planted with broccoli, cabbage, or spinach, for use in the winter or the following spring.

As soon as the crops have been harvested off the second section the ground must be trenched ready for the main crop of potatoes for the following year.



2. FIELD DRAIN WITH STONES AT THE BOTTOM

Choice of Seeds. The question of seeds and the correct time to sow them is of vital importance, and it will be found that in the long run it pays best to buy one's seed from a reliable nurseryman, and not from dealers or agents. This will ensure that the seed is fresh ; seed that is stale has lost much of its germinating power. Care should be taken to procure seed that is pure and true to its name. It requires years of experience to say with any authority to what particular variety seed belongs, but to test its germinating powers is a simple matter. The most satisfactory method is that employed by large nurserymen, and consists in planting a certain amount under favourable conditions, and watching results. The plots on which such seeds are grown are termed testing grounds. In this case the seed will be a year old when sold, but will still be fresh enough for good germination. A quicker though more rough-and-ready method of testing seeds is that described in the chapter on the Propagation of Fruit Trees. [See page 5566.] The term "freshness" needs qualifying, as certain seeds are as good, or even better, after they have been kept a year or more than when quite new.

Parsnips, onions, and leeks should be sown the first year after they have been harvested. The keeping power of other seeds is : TWO YEARS : Thyme, beans, sage, peas, rhubarb, carrots. THREE YEARS : Parsley, asparagus, spinach, lettuce, radish, endive. FOUR YEARS : Cabbage, broccoli, turnips, cauliflower, celery. FIVE YEARS : Beetroot, cucumber, marrow, tomato.

The vitality of the last four is such that they can be kept even for seven or eight years. These facts should be borne in mind, as some seasons are unfavourable for the proper ripening and maturing of seeds. In cold, wet summers it would be better to use older seed that had been properly harvested.

It may be of assistance to the small grower to know that if the prices for a particular crop in any season are low, it may pay him better to let it run to seed. In the case of annual plants such as peas, beans, radishes, lettuce, and the like, the seed should be taken from those first maturing. In the case of biennial and other plants such as beets, carrots, parsnips, onions, celery, and cabbages, the method of raising the seed is to select the best roots before the winter and replant them in the spring.

Early and Late Sowing Varieties. The novice or amateur may say that he has known some of these biennials go to seed the same year that the seed was planted, but in these cases it is safe to say that some unnatural factor has been at work. Seed sown too early, with a mild autumn following, may thus obtain a longer season and be induced to become annuals. In the circumstances it may be helpful roughly to divide the various seeds into two classes—those for early sowing and those for late sowing. *Early sowing* corresponds to the period when the average temperature in the shade is 45° F., which in our climate occurs from the middle of March till the end of April, varying, naturally, between the South of England and the North of Scotland and the West Coast and the East Coast. By *late sowing* is meant the period when the average temperature in the shade is 60° F., this being in our climate from the middle of May to the middle of June.

EARLY SOWING : Parsley, radish, lettuce, cress, turnips, parsnips, carrots, beetroots, onions, spinach, peas, celery, cabbage, cauliflower.

LATE SOWING : Beans, scarlet runners, marrow, cucumber, tomatoes.

Sowing. Seeds are sown in two ways, peas, beans, carrots, and the like being sown in drills, and such seeds as cucumbers and marrows in hills. On wet land, however, it is often advisable, in order to obtain better drainage, to sow on ridges seeds usually sown in drills on the flat, this being particularly the case with such seeds as turnips. It also has another advantage—that when the time for thinning out them arrives, the operation is performed with greater perfection.

On hot, dry, sandy soils it is of the utmost importance firmly to tread in the seed. This is done after the seed has been sown, by pressing down the soil with the feet so that the moisture cannot evaporate so quickly. This answers well where the sowing is on a small scale, but is, of course, quite impracticable in the case of fields. It is quite a common practice among farmers to roll the field with a heavy roller after sowing their crops on such soil. For vegetable seeds, however, a much better plan is to use three heavy iron wheels, mounted on an axle, the distance between the wheels being regulated according to the distance that the rows are apart. The tyres of the wheels should be about three inches wide. The axle is merely a round iron bar along which the wheels may be moved, being kept in the desired position by means of an iron collar on each side, with a set-screw to keep it from slipping [4].

The question may reasonably suggest itself as to why this trouble should be taken when a heavy iron roller would cover the ground more quickly. The answer is that a great advantage is gained, as only the ground immediately over the seeds is *firmed*, or pressed. This causes the seeds to germinate more

quickly than those of weeds in the surrounding soil which has not been firmed, so that the crop is up before the weeds, thus considerably assisting hoeing. By experiments it has been proved that seeds that have been firmed in will show through the ground in from six to eight days sooner than those not so treated; and when the question of the first hoeing is considered the advantage will be readily appreciated, particularly in the case of seeds like onions and carrots. If the soil is particularly light and the season dry, it is a good plan to fill the box that has been provided on top of the wheels with sand or earth, so as to weight the firmer.

There is no need to mention here the depth at which the various seeds should be planted, nor even the exact time at which they should be sown, as it is the practice of most seedsmen to furnish instructions when they send out their seeds.

The following tables, showing the quantity of seed and the numbers of plants required for an acre, will be useful:

3. CREOSOTED BOARD DRAIN

Note that the boards on the two sides are not nailed close together; a little space is left for the water to find its way into the drain.

QUANTITY OF SEED REQUIRED TO SOW AN ACRE

Sown in Drills		*Sown in Hills*	
Beans (Dwarf)	2 bushels	Cucumber	2 to 3 lb.
Beet ..	5 to 6 lb.	Marrow ..	3 to 4 „
Carrots ..	3 to 4 „	Pumpkin ..	4 to 6 „
Cress ..	2 to 3 „	Corn (Sweet)	8 to 10 quarts
Onion ..	5 to 6 „

The Field Marker. Some method of marking out the ground for vegetables must be adopted. Nothing is more unsightly than irregular rows of vegetable crops, and if the rows are not equal distances apart much valuable space may be wasted. Some market gardeners have a very rough and-ready manner of performing this operation. There are one or two machines specially manufactured to accomplish this, but for all practical purposes the one illustrated [5] will be found to be the best. The following are some of its advantages: As it has wheels, the worker can draw it across the field more steadily. The coulters, by means of set-screws, are adjustable in more ways than one. The bar on which they are fixed with collars and set-screws allows of those coulters that are not required being turned up out of the way—a better plan than removing them altogether and possibly losing them. They can be placed close together or farther apart without any measuring, the bar on which they are fixed being marked in inches. They can be regulated as to the depth they go into the ground, as they can be set perpendicularly from the horizontal bar or at an angle. The width of the drill they make can also be regulated by adjusting the coulters. There is an adjustable marker that can be fitted into either end of the horizontal bar; this travels in the last drill made, to give the distance for the next set of drills.

When the seeds of such vegetables as celery, cabbage, and cauliflower are growing in the seed-bed, it should be the aim to raise plants of a stocky or sturdy nature. One method employed to obtain this result is to cut off the tops of the young plants, which may even be done twice before the plants are set out. It also has the added advantage that the plants do not suffer so much when transplanted.

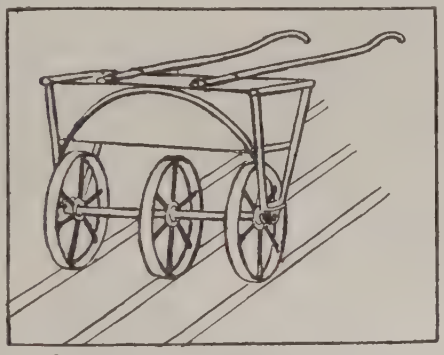
Transplanting. This is an operation that shows the advantage of the grower raising his own plants. The less time lost in removing them from the seed-bed to their permanent position the better, and it is surprising what lack of care a large number of growers show in this respect. Such factors as the condition of the soil of both the seed-bed from which the plants are to be taken and that of their new permanent home, the state of the weather at the time of transplanting, and the actual manner of transplanting all have a bearing on the success or failure of the crop.

Experience alone can give a knowledge of the condition that the plants should be in at this important stage of their life. It has been said that experience is the best teacher, though an expensive one. However, if strict attention is given to such details as keeping the seed-bed free from weeds and well cultivated, cutting the tops off the plants to keep them stocky, and, above all, if great care is exercised, in digging up the plants, to retain all the fibrous roots as far as possible and to see that the ground for their reception is moist, a great step will be taken towards counteracting any mistakes made from lack of experience. If, owing to lack of rain, the ground is short of moisture, the transplanting should be delayed as long as possible. If it must be carried out, the work should be accomplished towards the close of the day or when it is cloudy, so as to prevent as far as possible the plants from wilting. In such a case also it is more than ever important that the soil should be firmly pressed against the roots of the plants, and, if possible, a little water given to each plant to revive it.

Some people take a great deal of pains to press the soil around the plants with their hands, imagining that it is a better plan than that of pressing the soil against the plant with the dibble [6A and B]. This is bad practice, because it is aptsto leave the plant suspended [6C]; for a hole has been made with the dibble, the plant inserted, and the soil pressed with the hands probably only round the crown of the root, whereas if the dibble is inserted in the ground by the side of the plant the soil would be pressed against the whole of the roots, as well as the crown of the plants [6D]. It will be found a very good plan, when a man has completed planting a row, for him to retrace his steps, and with his feet tread the ground firmly around the roots. This applies more especially in dry weather.

In planting cabbages, lettuce, celery, and the like, it will be found economical to have a boy to go just ahead of the man who is planting, to drop the plants on the ground at even distances apart. The plants should be dripping wet when planted; the soil will then cling to the small roots, and the leaves of the plant, being wet, will be in a better condition to withstand the drying influences of the air.

In the cultivation of vegetables, it is imperative that the hoe and shove-shim be kept busily employed to keep down the weeds and to aerate the soil. Vegetables cannot be grown profitably if weeds are allowed to have sway; and the more the land is manured, the more will the weeds have a tendency to assert themselves. This is the case especially where stable manure has been used, as seed from both the hay and the corn fed to the horses is apt to fall to the floor from the manger and be swept up with the manure.



4. ROLLER FOR VEGETABLE SEEDS

Preparation and Maintenance of Hot-beds. If a grower intends raising his own plants, he must of necessity have some means of forcing, so as to have the plants ready when they are required, because in many instances this could not be done in the open air. Large growers will use forcing-houses; but as the beginner may find that one of his difficulties at the start is a lack of capital, he will find that a hot-bed will answer his purpose at less expense. A *hot-bed* consists of a raised bed of manure covered with soil, on which is placed an ordinary garden frame. The material used for preference should be horse manure, fresh from the stable, to which has been added, if available, an equal quantity of rotten leaves. Naturally, the manure and leaves must be thoroughly well mixed, and the whole should be firmly pressed down.

The various stages or operations connected with the formation of a bed of this description are as follow: A position must be chosen with a southern aspect, preferably slightly on the incline, care being taken to see that it is sheltered from cold winds and thoroughly dry. The materials to be used should be those technically known as "sweetened," a condition secured by forming them into a heap and several times turning them over and wetting them. The ground is then marked out to the size desired for the bed. It should be at least 1 ft., and, if possible, 18 in., wider all round than the frame that is to be used. It should be understood that the frames are made movable. They are made somewhat like a box, and a convenient size is 9 ft. long and 6 ft. wide, so as to take three sashes (that is, glazed tops or sliding lids) each 3 ft. in width and 6 ft. long from front to back, that being the length of the sashes. The depth of the frame itself in front should be from 15 to 18 in., and at the back 24 in. The reason for the difference between the height of the back and the front is that it causes the sashes to be on an incline, thus giving them the requisite angle for attracting the sun's rays, and allowing the rain to drain off.

In Fig. **14** it will be noticed that there are two frames of this description, on which five of the lights, or sashes, have been pushed back, the sixth being the only one actually in position, thus showing clearly the cross-pieces on which the sashes rest. Obviously, the sashes should fit as tightly as is compatible with easy working, so as to exclude the frost, and the ends of the frames should be high enough to stand above the thickness of the sashes, so that frost or cold air is prevented from penetrating.

The minimum depth of the hot-bed itself on which the frame rests should not be less than from 3 to 4 ft., and should be slightly higher at the back than at the front. The frame having been placed in position, the sashes are kept on until the heat rises to about 100° F. It will be readily appreciated that this is too high a temperature for vegetable life, and owing to the wetting of the manure before the hot-bed was made a good deal of rank steam will be given off by the fermentation. For this reason the sashes must now be removed, that this steam may be allowed to escape.

A word of warning must be given to the beginner who may be a little impatient—he will be liable to lose his first crop by planting a sowing before this excessive heat and rank steam have been given off. This process often takes three or four days. The temperature should never exceed 90° Fahrenheit.

The surface of the manure on the hot-bed should be covered with about one barrow-load of good loamy soil to each division of the frame, care being taken to see that it is of even thickness over all the manure. The sashes should then be replaced. Having sown the seed or planted the plants, great care must be taken to maintain an even temperature. This is accomplished by placing mats over the frame at night and on windy, wet days. It may be found necessary, to maintain the temperature, to add coatings of fresh manure, known as "linings," which are piled up round the bed on all sides. The temperature of the hot-bed should be maintained at an average of 75° F., and immediately it falls below this old linings should be taken out and replaced with fresh ones.

Cold Frames and Their Uses. Cold frames consist simply of two boards running parallel and nailed to corner posts to keep them in position. Spare sashes or lights are used as a top covering. The back board need not be more than 10 in. to 1 ft. in height, and 7 in. will be sufficiently high for the front board. As with the frames used on hot-beds, this difference in height between the front and back boards is in order to have the sashes or lights on an incline. The length

of these cold frames is of little importance, provided that they are in multiples of 3 ft., which is the width of a sash. It is a matter of some importance that they should be sheltered from the north-west, and if the position is not naturally protected a fence about 6 ft. high should be erected. The aspect of the sashes should be south, or at least south-east. The ground space under each sash being 3 ft. by 6 ft. will be sufficient to hold about 500 cabbage or cauliflower plants or 800 lettuce plants. As these plants belong to the hardy class, they will be uninjured except by very severe frosts. They must, nevertheless, be treated as naturally as possible. To do this, the sashes should not be put over the young plants—which would be planted in the frames during October—until severe weather arrives, usually about a month or six weeks later. Should a sharp spell set in, the sashes may be placed on the frames, but care must be taken to remove them as soon as the cold snap breaks up, so as to harden the plants for the winter. During severe winter weather the sashes will have to be replaced; but even though the temperature drop from 5° to 10° below freezing point, they must be raised at the back for an hour or so during the day, so as thoroughly to air the frames. This can be done by placing a brick or block of wood under the sash at the top.

Another use to which sashes can be put is to fill spare frames with straw or leaves, which will keep the ground moist and protect it from frost, so that at the end of February the lettuce plants that have been in the frame all the winter can be thinned out and transplanted to the spare frames. This will naturally give them a check, and if the nights were cold or frosty they would certainly perish, but, protected for a time with the sashes, properly aired, and the sashes opened when rain falls, so that they may be thoroughly watered, they will be ready for market in about six weeks, and should fetch a high price.

Spare frames can also be used for planting seeds of hardy vegetables, or even cucumbers, utilising the spare sashes to protect them, and in a measure to assist their growth.

Protecting Cloth Instead of Sashes. Many a market gardener has saved a good deal of money by using cloth for covering his cold frames instead of using the glazed sashes. It will readily be seen that this method, though cheaper in the original cost, requires more labour. The lighter the material is in colour, the better the light will penetrate. As light is one of the hardening agencies, it will mean that the cloth must only be placed over the frames when the weather is very severe, for if light and air are both excluded the plants will not be hardened, but, on the contrary, will be weak and susceptible even to slight frosts. Some growers use matting over their sashes as an added protection in very severe weather, but if the plants have been gradually hardened this should not be necessary, and in a large number of cases it has done more harm than good, because it has been left on too long, and has therefore excluded too much light. This does not apply to hot-beds, which, as we have seen, are very different from cold frames.

Chemicals and Vegetable Crops. The question of soils and their mineral constituents has been already dealt with; and as certain soils require certain chemicals that others do not need, so, with vegetables, some require chemicals of a very different nature from others.

Vegetables may roughly be divided into two classes: (1) Those in which phosphates and potash very largely predominate, and (2) those in which sulphur, soda, and salt are also found to a considerable extent. The following table shows approximately the proportions in each, and is based on the average amounts remaining in the form of ashes after a sample has been burnt.

Vegetable.	Phosphates	Potash	Soda	Salt	Lime	Sulphuric Acid
Class I.:	Per cent.	Per cent.	Per cent	Per cent.	Per cent.	Per cent.
Pea	36	40	—	—	—	—
Bean	30	40	—	—	—	—
Potato (tubers only)	19	59	2	—	2	6
Parsnip	18	36	—	5	11	—
Carrot	12	36	—	—	—	6
Jerusalem artichoke	16	65	—	—	—	—
Class II.:						
Cabbage	16	48	4	—	15	8
Turnip	13	39	—	10	10	14
Beet	14	49	9	20	6	5

Lentils belong to the first class, while broccoli, cauliflower, and kale belong to the second class.

This table shows roughly what chemicals the different vegetables require for their proper nourishment. Clayey and loamy soils in most cases contain an abundance of potash and phosphates; hence, if it is desired to grow vegetables mentioned in Class II., the other ingredients must be added. In sandy soils, however, phosphates and alkalies are lacking; therefore it follows that, instead of using manure which can be more profitably employed upon loamy soils, it will be found that a mixture of kainite, which is a form of potash, and superphosphates of lime will yield better results. Particularly is this the case with crops like potatoes, onions, and carrots, which favour sandy soils. Sulphate of ammonia can be mixed with superphosphates, and for that matter with any acid manures, but never mix either of them with basic slag or nitrate of soda, for ammonia may be given off as a gas.

Asparagus. Most of our common vegetables are annuals, but there are some perennials, of which asparagus is one. The usual practice is to grow it from seed. This is easily obtained from existing beds, as it yields abundant seed in the autumn. The method of harvesting the seed is to wait until the berries are quite ripe, which is when they are a deep red in colour, and then to hang them up to dry. They should next be rubbed out through a sieve so that the pulp passes through the sieve, leaving the seed behind. The seed-bed must be carefully prepared by deep digging, followed by a moderate dressing of well-rotted manure. It is a mistake to make the seed-bed too rich; it can always be improved by a top dressing in succeeding years. The seed should be sown in April or May, in rows one foot apart, and it is of the utmost importance that the young plants be kept well hoed and free from weeds. If a bed is neglected it may take two years to raise as large plants as might be grown in one year.

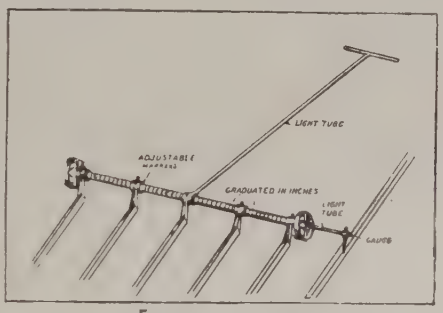
The first year the plants will make very little top growth, as the roots develop first. The permanent bed is made in September, and one of the best forms of beds is five feet wide, with three rows of plants—one row down the centre of the bed, with a row on either side. The outside rows should be

12 in. from the edges of the beds, leaving 18 in. between the centre row and those on the outside. The plants should be 9 in. apart in the rows, and the crown of the root should be covered with about 3 in. of soil. It is a very good plan to rake over the bed a week or so after planting, so as to destroy any weeds that may have germinated.

Asparagus will be found to benefit greatly by an application of salt—1 lb. to 5 sq. yds.; and a top dressing of manure should be given every spring, during the month of March. Whatever other vegetables may succeed with weeds, asparagus will not; it cannot possibly be made to pay if weeds are allowed to grow. The beds should always be thoroughly cleaned before the winter.

Globe Artichoke. There are two kinds of artichokes, the globe artichoke and the Jerusalem artichoke. The former is really the true artichoke. It is a most accommodating plant, and it has been said of it that it can be treated as an annual, biennial, or perennial, but it is as a perennial that it is chiefly grown. It can be grown from seed in a rich, moist soil, and is one of those plants that greatly benefit by saline manures. After plants have been grown from seed they can easily be increased by suckers, but a bed, having once been established, will remain in bearing for several years.

The portion of the plant which is used as a vegetable is that of the undeveloped flower-heads, which are boiled. Artichoke chard is another form of it. If the plant is cut down to about a foot from the ground early in July, about September a great deal of young growth will have been made, and this young growth is then tied moderately close together and the soil banked up so as to exclude the air, whereby the shoots are blanched.



5. FIELD MARKER

Jerusalem Artichoke. This is entirely different from the globe. In fact, it belongs to another tribe altogether, and perhaps the only reason that it is called an artichoke is because it resembles its namesake in flavour. Its appearance in growth is very similar to the sunflower, to which tribe it belongs. In this case it is the roots or tubers which are eaten. They resemble knotted potatoes. It is quite hardy, and can be dug in November. As a vegetable it is not to be despised, as its nutritive value is equal to that of the potato, which its culture in all respects resembles. Strange to say, it appears to be absolutely immune from disease, and will grow in almost any soil. In certain districts it is grown for the pigs, who root it up for themselves.

Broad Bean. This is one of the hardiest plants of the kitchen garden, and, like peas, can be sown in October where the soil and situation are favourable. A succession can be sown in January, but for the main sowing it would be better to wait until March. Broad beans should be sown in rows about 4 ft. apart, which leaves room for a row of spinach or lettuce in between. There are three classes—the Mazagan, the Longpods, and the Windsors. The first-named are generally sown in the late autumn, the second early in the year, and the last as late as from April to the end of May.

Dwarf or French Kidney Beans. These prefer a good but light soil. The best time to sow is towards the end of April, from which time a succession of sowings may be made until the end of July. One point to remember is that they should not be overcrowded, which is a very common error to be guarded against. They should be planted in rows 2 ft. apart, and care should be taken in their gathering to see that none are left, for they will soon cease to bear if any are allowed to run to seed.

Runner Beans. With the exception that these require more room, their cultivation is the same as for the dwarf. They are planted in single rows, which should be 5 ft. apart, but it is a common practice to grow them in double rows. In this case there should be 9 in. between the two rows, the double rows themselves being 6 or 7 ft. apart.

Beetroot. March should not be allowed to pass without making the first sowings of beet. This is sown in drills 15 in. apart. Care should be taken to tread the soil firmly. They are thinned out from 9 to 12 in. apart. In this operation it is not of so much importance to leave the strongest plants as to leave those that have the best colour, and it is essential that the work should be carried out as soon as possible. In digging up the roots it is vital that they should not be broken, or they will bleed, and their appearance will be spoiled for salad.

By September some of the roots will be ready for lifting, and they should all be dug before November. It is possible to leave them in the ground through the winter, provided that they are covered with litter, but it is not advisable to do so unless absolutely necessary, as they are apt to be injured by frost if the weather is very severe.

Broccoli. It is a wonder that this vegetable, which is so closely allied to cauliflower, should ever have been separated from it. Cauliflower, it is true, is generally planted for summer use, and broccoli for use in the autumn, but there is no reason why one should not do as well as the other in either spring, summer, autumn, or winter.

The grower will soon find that if he intends to cultivate broccoli successfully his land must be in a good state of fertility, as is the case with nearly all the cabbage tribe. Sow the seed on carefully prepared beds; and when the plants are large enough to set out in the field have 2 ft. between the rows and from 18 in. to 2 ft. between the plants in the rows. Thinning and planting out must not be neglected, or the plants will be spoiled.

Autumn Broccoli. The seed of this should be sown in frames in February and March, and in the open in April.

Winter Broccoli. This should be sown during April, but care should be taken that it is not left too late. The seasons vary so much that due allowance must be made for the fact. Do not hesitate to plant out as soon as possible, for although to a certain extent it does not interfere with the time that they will be ready for cutting, yet it does influence the size of the heads.

Spring Broccoli. Broccoli being easily affected by climatic conditions, there is no certainty with the spring variety. Warm spells of sunshine may tempt it forward, late sorts thereby being ready for market before they were expected. The seed for this

should be sown in April and May, and it is always advisable to make at least three sowings, the most important being made in April.

Summer Broccoli. Many growers feel that this class need protection during the winter, but experience shows that, in nine cases out of ten, it is better to let them take care of themselves, and certainly the best crops are obtained when they have been left undisturbed. Perhaps one of the greatest advantages of summer broccoli is that it comes in just before peas, and as a consequence is always welcome in the markets, particularly as it is generally well over before the bulk of the peas are on sale. The seed is sown in May, for the heads to be ready to cut in the June of the following year.

Sprouting Broccoli. Perhaps of all the vegetables most welcome in the winter and early spring sprouting broccoli will rank first; it is a favourite with growers, because it is easily grown, is very hardy, stands the winter well, and is exceptionally free from injurious insect pests.

Brussels Sprouts. March is really the month for sowing these, although a succession might be sown in April for late supplies. To obtain perfection they should be sown early, so as to give them a long time for developing. The plants should be ready for transplanting in from eight to ten weeks from sowing the seed, and the plants are set out at about 20 in. apart. The soil that suits them best is a stiff, rich loam, and, as with other plants of this nature, they should be constantly hoed.

Cabbages or Brassicæ. These really include the ordinary cabbage, Brussels sprouts, savoys, red cabbage, borecole, curly kale, broccoli, and cauliflower, and their treatment, both as regards raising the seed and their after-cultivation, is very similar. The seed-sowing times are in April for summer use; June and July for autumn and winter use; August and September for spring use. Never have a seed-bed near trees or hedges, but as much in the open as possible [9]; and care must be taken to see that not only the seed-bed but their permanent home also is well drained. The seed should be covered with sifted soil and well trodden in.

As soon as the seed comes through, it will require constant attention to keep the bed free from weeds, and, if the weather should be dry, to be ever ready with the watering-can to keep it moist. Give it a good soaking, and not simply a sprinkling—this will tend to make the plants sturdy. The seed-bed will profit by an application of lime, salt, or soot, which will not only help the growth of the plants, but prevent attacks by injurious insects. The process of thinning them out should be attended to as soon as the plants are large enough to handle.

Red Cabbage. This is generally only grown for pickling purposes; its cultivation is easy, being the same as for the ordinary cabbage. As soon as the head is thoroughly formed it will be ready for cutting.

Savoy Cabbage. The curly green leaves of this variety of cabbage are very attractive, and it is noted for its leaves and close head, and is useful for growing between rows of peas.

Curly Kale, Borecole. There are several varieties of this, and it is sometimes spoken of as "sprouts," on account of the curly sprouts which grow up the stem. Some varieties are green in appearance, while others are purple. They are tall in growth, and require more space than ordinary cabbage, being planted from 2 to 3 ft. apart, according to the variety.

Cauliflower. The cultivation of cauliflower is almost identical with that of broccoli and cabbage, and is certainly one of our favourite English vegetables, the delicate white head being the attraction. Its head is more compact and the stem shorter than that of broccoli [10].

Carrots. Carrots are not only grown for our markets, but there is also a large tonnage grown for the feeding of horses and cattle. Again the importance of keeping the ground free from weeds must be emphasised, as in their early life carrots are of comparatively feeble growth, and a great injury will result in respect of the yield per acre if this matter is not attended to.

The most general method is to plant them in drills 14 or 15 in. apart, and to thin them out to 3 or 4 in. in the rows, though some growers prefer to sow them broadcast. A deep, light soil with chalky tendency suits them best, and the seed should be sown as shallow as possible, the land being treaded afterwards to make it firm. A calm day should be selected for sowing the seed, as it is very light and apt to be blown about if it is windy.

The earlier varieties may be sown in February, a sheltered position being selected, and the main crop about the end of March. The seed takes from a fortnight to three weeks to germinate. They should be thinned as soon as possible, and the soil frequently hoed to keep it loose. If the carrots are required for storing it is advisable to leave them in the ground until the end of October, or even the early part of November.

Celery. This is one of the crops that should be in favour with all small-holders and market-gardeners, as it brings in a return at a time of year when there is not much else coming into the exchequer, but failure will inevitably result if its cultivation is undertaken lightly; and unless the grower can afford to feed the ground well he had better leave it alone altogether. February is the month for making the first sowing, which is followed by successive sowings up to May. The first is made in a gentle heat, and the latter in a warm, sheltered position outside. Celery requires a rich, deep soil and cool, moist atmosphere.

As soon as the plants are large enough they should be transplanted to a cold frame or shallow trenches. The ground of their permanent position must be carefully prepared. First of all, it must be trenched and well manured. Just before the plants are ready for planting out, a trench should be dug to a depth of from 12 to 18 in., the soil thrown out being laid in a ridge on either side and a layer of well-rotted stable manure being placed in the bottom. Early in July the plants are set in the bottom of the trench about 6 in. apart, and, if possible, it is well to water them for a night or two, until the plants begin to grow, which will usually be in two or three days. This is still more important if the weather is dry.

There is very little to do after celery is once planted except to keep the ground free from weeds for six or seven weeks. About the middle of August it will be found necessary to begin earthing up—that is, filling in the trench with the soil that has been thrown out, and gradually, as the plants grow, banking them up on either side with earth. This operation is to blanch or whiten them, and will have to be continued about every week or ten days until the earth is banked up nearly to the top of the plants, so as to keep the leaves upright and prevent them from spreading. With the coming of September the first sowings should be ready for market [11].

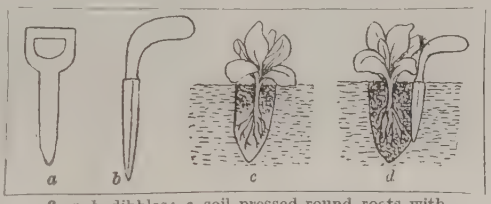
Cucumbers. There is a very general impression that cucumbers cannot be grown successfully out of doors, but this is a great mistake, for although the outdoor varieties are not of such good appearance, and are smaller than the indoor varieties, they are quite equal to them in flavour. Only those varieties known as "Ridge" cucumbers are suitable for growing in the open, and are useless for exhibition purposes.

They are grown on hills or ridges. The best method is to throw up a ridge with the plough, having previously given the land a liberal dressing of manure. The seed can be sown directly on these ridges, but if a cold frame or hot-bed is available it will pay to raise the plants by this means and then transplant to the ridges. They are ready for moving as soon as they have obtained two or three of their rough leaves, which is usually about three weeks after sowing. Sow about the middle of May.

It will be found of great benefit to the young cucumber plants if a row of runner beans are planted on either side of them to act as a shelter from the cold winds. Cucumbers can be grown on hot-beds or under grass all the year round, but a temperature of between 70° and 75° F. must be maintained. To obtain any fruit from cucumber plants grown under glass, the flowers will have to be fertilised by hand, particularly during the winter. In the open air this work is performed by insects, the wind, and rain.

Gherkins. These are a small variety of cucumber which are used exclusively for pickling. They are only 2 or 3 in. in length, of strong growth, and should be planted 5 ft. apart.

Horseradish. There is generally a good demand for this root; it is easily grown, and without much expense or labour. The best method of propagating it is to obtain some old roots and cut off the smaller rootlets or side shoots; these rootlets should be cut into lengths about 4 in. long, the top end being cut square, and the lower end slanting—this will prevent it being planted upside down. If planted the wrong way up, it would grow, but would not make such a good root.



6. *a*, *b*, dibbles; *c*, soil pressed round roots with hands (wrong method); *d*, soil pressed against roots with dibble (right method).

The soil should be prepared before the winter by being deeply trenched. Holes should then be made with a dibble, about 1 ft. deep and 1 ft. apart in the rows, the rows themselves being 2 ft. apart. Insert the rootlet, or *set*, as it is termed, when it has been prepared in the manner indicated, taking care that the set is at least 2 or 3 in. below the surface. Press the soil well into the hole. It is a hardy plant, and one of the last to be dug before the winter.

It is prepared for market by cutting off the green tops and washing the roots, removing all the smaller rootlets which are used as sets for another crop.

Leeks. These vegetables [8] are grown almost exclusively as a second crop. A light, rich soil will be found to suit them best; in fact, the soil can scarcely be too rich, and in moist land they will grow to a great size.

April is the month for sowing the seed, which is sown in drills about 12 in. apart. As soon as practicable, they are thinned out to 5 or 6 in. apart in the rows. As soon as the first crop has been gathered, which is usually about July, the ground must be thoroughly prepared by ploughing and harrowing, and the leeks set out as in the seed-bed, 12 in. between the rows and 6 in. apart in the rows. As the plants grow they are earthed up in much the same manner as celery, in order to blanch them. They are hardy vegetables; 20 to 25 deg. below freezing will not injure them.

Lettuce. This is easily grown, and as a rule is less troubled by insect pests than almost any other of our green crops. It may be divided into two classes—(1) the cabbage, or low, round-hearted variety; and (2) the Cos, or tall, upright form.

Lettuces require a loose, rich loam, and manure must not be stinted. The seed should be sown in drills 12 in. apart, and, while the plants are quite small, thin them out to 2 in. apart. Later, thin them out again to about 6 or 8 in. apart. Sow the seed thinly and transplant those pulled up in the thinning. Begin sowing in February with monthly sowings up to July, for cutting in the spring and summer, but for winter and early spring cutting the seed should be sown in August and September.

The Cos variety is of very little service for winter cutting, as the plants are apt to rot off when tied up. This is the usual practice resorted to by growers in order to give them crisp, white hearts. It is a simple operation, consisting in tying a piece of bast round the centre. Care should be taken not to tie them up more than two or three days before they are required for market, as it causes them to run to seed. This attention is not required in the case of the cabbage variety, which, being more hardy, are better suited for winter cutting.

Marrows. These are very susceptible to cold, and the young plants in particular like a warm situation. A rich soil is also required; otherwise their cultivation is simple. The seeds are sown in pots or frames during April or early in May, and transplanted when they have four leaves, planting them out early in June. The seed may be sown in the open towards the end of May or beginning of June. It is advisable to peg down the bines at a joint, from which they will strike root and thereby add vigour to the plants.

Onions. The simplest method with regard to onions is to grow them from seed, though they are grown from *sets* as well. The seed is sown in drills 9 in. apart and ½ in. deep during February and March, but for a supply in winter and the following spring the seed should be sown in the early part of September. The silver-skinned variety, which are used for pickling, are sown towards the end of April or beginning of May, and should be grown in poor soil. The other varieties, however, require a well-manured soil, and it is very essential that the soil should be well pulverised and rolled flat.

The practice of firming the soil after sowing is very impotant with this crop, as when the seed first pushes its way through the soil it is very difficult to see if any weeds have been allowed to grow.

Parsnips. The end of February should see the first sowings of this seed, with sowings for the main crop in March, and they naturally require a deep soil, so that their roots can push down into the ground without any trouble. The seed is sown in shallow drills 18 in. apart. Land that has been well manured for a previous crop suits them best,

as they have a tendency to produce forked roots on freshly manured soil. They are thinned out to 9 in. apart in the rows.

Peas. Peas prefer a warm, light soil, not too generously manured. The seed should be sown fairly thickly, as mice are apt to steal them out of the ground. The usual practice is to sow the seed in drills about 2 in. deep, the drill being 4 in. wide. The distance between the rows varies according to the height to which they grow, but with the dwarf varieties the rows are generally about 2 ft. apart, while with the taller kinds the rows are generally from 4 to 6ft. apart. In the latter cases it will be found more economical to plant such things as lettuce, radish, spinach, or even vegetable marrows between the rows.

Birds are great depredators of peas as they begin to shoot, and a very good plan to prevent loss in this manner is to stretch black cotton along the rows.

Potatoes. These form by far the largest crop of a kitchen garden. [See page 705.]

They are propagated by *sets*, or *seed* potatoes, which are really medium-sized potatoes that are clean and healthy. They are planted in deep drills or furrows, about 4 in. deep, the rows being about 3 ft. apart, and the sets 10 or 12 in. apart in the rows. A noticeable feature about early potatoes is that they germinate and ripen quickly, but do not keep so long, and their chief use is to give a supply until the main crop is ready to dig. Some people dibble in the seed, but it is not to be recommended, and should positively be avoided on clay soils, for the looser the soil the better it will suit the potatoes. As soon as the shoots are 4 or 5 in. above the ground, they should be hoed, the soil between the rows dug over, and some of it drawn up against the plants. A plough run up between the rows will effect the same result. When they have grown eight or more inches high, this operation should be repeated.

Radish. The radish is what might be termed catch or auxiliary crop, scarcely interfering with a the main crops at all. For instance, it can be sown between rows of peas or on the sides of celery trenches. There is always a large and ready market for radishes, though the work of tying them into bunches requires a good deal of labour.

As with most crops, the earlier that they are placed on the market the better the price will be. To obtain them early, a light, rich soil will be required. Heavy soils should be avoided, as they only produce an inferior article. They can be sown broadcast or in shallow drills, these being from 4 to 6 in. apart, according to the variety, the long radishes or small turnip sorts not requiring so much room. It is a great mistake to sow them too thickly, as the roots will then be small, hard, and stringy.

The first sowings may be made in the latter part of January, but all early sowings should be protected from frost by litter, as if they do not grow quickly, or if they receive a check, they will be hot and tough. Successive sowings may follow. The Black Spanish or winter variety are sown in July.

Rhubarb. Easily cultivated and requiring little attention, rhubarb is propagated by dividing old roots either in the autumn or early spring—the former for preference. It is obvious for a plan of this nature that the ground should be well trenched and manured.

The plants are set about 4 ft. apart, and should be well watered for a day or two after planting. Rhubarb should never be pulled the same season that the roots were planted, as this spoils both the colour and the flavour. To obtain an early supply, the roots should be covered with litter and large pots—grape-barrels, which can be obtained from any greengrocer, being most useful.

Shallots. This vegetable is well known as a substitute for onions, but it may not be well known that when well cultivated the clumps grow bigger than a man's fist, and the individual bulbs will be as big as a chestnut. Here again is another instance of propagating by division, the bulbs being separated from the clump and planted in rows about 9 in. apart, September being the most suitable time to plant them, as they take a long time to grow. They make but slight growth before the winter, but develop rapidly with the opening of spring. They should be pressed firmly into the soil, but not buried. One great advantage of shallots is that, being hardy, they are ready for market at least three weeks before onions. They are very prolific.

Spinach. This is a very important crop for market gardeners, requiring but little culture, and is what might be termed an all-seasons vegetable. It can be sown in early spring as an auxiliary crop between rows of cabbage, peas, or beans, and under suitable conditions is ready for cutting in four or five weeks. The first sowings should be made early in September, so that it has obtained a hold before the winter sets in; this gives a vigorous early crop in spring. The seed should be sown in drills about 1 ft. apart.

At the end of January or early in February more sowings should be made. The seed should be sown thickly, using from 10 to 15 lb. per acre. The frost may cut some of it, and, if not, the extra crop dug in as a manure will always be found to be profitable. It requires a light, rich soil that has been well drained and well manured. The prickly seeded variety is sown in the autumn and the round seeded varieties in the spring. The leaves should be cut as soon as they attain a fair size, as they soon run to seed. It is most important to keep the ground free from weeds.

Tomatoes. To grow these with any degree of success out of doors, a hot, dry summer is required, plenty of sunshine and a good circulation of warm, dry air being essential. The seed is sown in pots in February under glass with the temperature at from 60° to 65° F., and the young plants require hardening off late in May for planting outside. They should not be transplanted into the open, however, before the beginning of June. The best method is to plant them in rows 4 ft. apart, and the plants themselves from 2 to 3 ft. apart in the rows.

During the fruiting season they require a plentiful supply of water at their roots, and the surface of the soil should always be kept well pulverised and free from weeds. As soon as the plants have been planted in the position that they are to occupy permanently they should be staked, care being taken to see that the stake is driven firmly into the ground. The stakes should be from 5 to 6 ft. long, according to the nature of the soil, 4 ft. being above ground and about 2 ft. in the ground. On a stiff, heavy soil from 12 to 18 in. will be found sufficient for the stake to be in the ground.

Regular attention should be paid to the tying; and as soon as the early flowers have set, the main stem should be topped—that is, the top pinched out of the head and the side fruiting branches kept short beyond the fruit.

Turnips. A well-manured, deep, sandy soil will be found the best for turnips. They can be sown from March to July in shallow drills, but for pulling

in winter and spring the seed should be sown during August. One of the greatest favourites as a substitute for greens in the spring are the young tops of the turnip. They are not a difficult crop to grow, but they must grow quickly; and to assist them they should have a dressing of lime in one form or another. Old plaster or mortar from building refuse will be found useful for digging into the soil in preparing it for the crop. They need thinning in good time—in fact, almost as soon as their first rough leaves appear. [See page 704.]

Herbs. As no kitchen garden is complete without an assortment of herbs, a few notes on their cultivation will be found useful.

Balm. This herb is a perennial, and can be grown from cuttings. At the same time, it may also be treated as an annual, and grown from seed, the seed being sown during May.

Sweet Basil. An annual, and one of the most popular herbs for flavouring purposes. It can be sown in the open ground in April, being planted in rows about a foot apart, and the plants should be thinned out to 8 in. apart.

Bush Basil. The treatment for this herb is the same as for Sweet Basil, the difference being that it is a dwarf-growing variety, and hardier.

Marjoram. This is a great favourite in all kitchens. It is generally sown about the beginning of April, the plants requiring to be a foot apart in the rows and between the rows. Like balm, it is, strictly speaking, a perennial, but can be grown as an annual. It is used in the green and the dried states.

Mint. This is sometimes spoken of as pea-mint or spearmint, which distinguishes it from peppermint. It is propagated by division, and should be planted in damp soil, in rows a foot apart. The runners should be kept cut back, or else it will run all over the ground; and it is advisable to make a fresh bed every two or three years, or else plough it in very shallow, otherwise the leaves are apt to become wiry and small.

Peppermint. The cultivation of this is the same as for spearmint.

Parsley. This herb requires plenty of room, and also a rich, damp soil, to grow to perfection. The seed can be sown any time from February to July. It can be sown as a border or in a bed in rows a foot apart, thinning out from 4 to 6 in. It should not be allowed to run to seed, and to prevent this it should be kept cut over.

Sage. This can be grown from seed sown in the open ground during April and May, and, like most herbs, it is best sown in rows, the plants being thinned out to 6 in. apart [7].

Summer Savory. Another useful herb for flavouring purposes. It is an annual, and grown from seed sown in drills a foot apart during April, the plants being thinned out to 6 in. apart.

Common Thyme. This is another of our English aromatic herbs, and a great favourite in all gardens and kitchens. The seed is sown in April, and the plants make a very effective border. It can be grown from seed or by division.

Lemon Thyme. This plant can only be propagated by division. It is aromatic, and always finds a ready sale. It should be planted in rows a foot apart, leaving 6 in. between the plants in the rows and, like most herbs, prefers a damp, rich soil.

Work Among the Vegetables Month by Month. Below we give a programme of the work to be carried out during each month:

January.—The ground as far as practicable should be thoroughly dug over and trenched. Early peas and broad beans may be sown in sheltered positions. If there is a spare frame, early ash-leaved potatoes should be planted.

February.—Any ground that has not already been dug should be attended to as soon as the weather allows, and towards the end of the month early potatoes may be planted in the open. Any warm spots and sheltered corners may be sown with early crops.

March.—This is the first month for sowing in earnest, and the main crops of the following may be sown: Peas, beans, onions, carrots, spinach, cabbage, radishes, and the like. The young plants in the frames need attention, and should be thinned out and horseradish planted.

April.—The hoe and shove-shim must be busy keeping down the young weeds as they grow. Seed-beds should be carefully watched, and, if the weather is dry, must be watered. Sowing and planting must be attended to, and young cabbage and lettuce plants may be ready for transplanting. Globe artichoke suckers should be planted, and asparagus beds receive a dressing. No time should be lost in sowing seeds or in obtaining plants. Herb seeds will do better if sown this month than almost at any other time.

May.—This is the month for dividing rhubarb roots for making a fresh bed. Tall-growing varieties of peas must be staked, and others sown. Onions, carrots, parsnips, and the like should be thinned out. Lettuce of the Cos variety should be tied up, to give them good hearts. Early potatoes will be ready for earthing up, and it would be well to bend the outer leaves of cauliflowers over the heads as they appear, to keep them white. The main crop of beet should be sown in the earlier part of the month. Dandelion, which is such a welcome addition to the salad-bowl, should be planted now.

June.—We look to this month for some of the first fruits of our labours, such as early potatoes, carrots, peas, cauliflowers, and even beans. There is still time to sow peas and beans, and the earthing up of potatoes should be continued. Cucumbers for pickling, lettuce, cabbage, and the like, should be sown; these will be of great value for planting out when the summer crops have been gathered. Every advantage should be taken of showers for planting out broccoli, lettuce, cauliflower, as well as celery.

July.—Vacant ground should now be prepared for autumn and winter crops. A few dwarf and runner beans can be sown, but it is not advisable to sow many, as they may be cut with the frost just as they are coming into bearing. Radish, turnip, lettuce, prickly seeded spinach, and parsley seed for winter crops should be sown, and more celery, leeks, and broccoli planted out. Early potatoes will be ready, and should be taken up to make room for autumn and winter crops.

August.—Give a liberal dressing of lime among cabbage, etc., to kill slugs and caterpillars. Earth up leeks and celery; cut down the stems of gathered artichokes; hoe and thin out turnips; take up and lay out to dry onions as soon as the tops begin to wither. Plant out sprouting broccoli, savoys, curly kale, and Brussels sprouts; sow Welsh and Spanish onions, cabbage, cauliflower, and parsley for next year's crop. Lettuce and turnip may still be sown in the earlier part of the month, and the celery should continue to be earthed up, but care must be taken that the soil does not get into the heart. Second early potatoes will be ready, and need digging.

September.—Plant out cauliflowers, cabbage, broccoli, and the like, and dig up first sowings of

FROM MARKET GARDEN TO CITY MART

LOADING UP FOR A MIDNIGHT JOURNEY TO TOWN

A BUSY SCENE AT COVENT GARDEN MARKET

main crop potatoes, continuing to earth up celery as required; it takes from five to six weeks to blanch celery properly. Thin out the vegetables sown last month.

OCTOBER.—Take up carrots, parsnips, beetroots, turnips, and the remainder of potatoes, and winter greens should be transplanted. Cabbages and savoys should be earthed up to the first leaves.

NOVEMBER.—Trench and ridge unoccupied ground and cover with manure. Peas and beans may be sown in sheltered places for the following year. Burn all rubbish such as bean and pea vines, potato tops, and the general rubbish connected with vegetables. Asparagus beds should be thoroughly cleaned, and celery will be ready for digging, and also horseradish that is required for storing through the winter.

DECEMBER.—With this month we expect frosts, and as soon as the ground is hard seize the opportunity to wheel out manure. When the weather is open and fine, continue to trench and ridge, that the frost may do its work and the land receive the full benefit of this great help in pulverising the soil. Avoid working on the land when it is sodden with wet, as it is liable to do more harm than good, particularly on some heavy soils.

The Choice of Seeds. Here is a list of the best kinds of the various vegetables and the order in which they should be sown:

ARTICHOKE. *Plants:* Green Globe, Purple Globe. *Tubers:* Sutton's White Jerusalem.

ASPARAGUS. True Giant, Connover's Colossal, Argenteuil.

BEANS. *Broad:* Sutton's Mammoth Longpod, Bunyard's Longpod, Exhibition Longpod, Green Longpod, Sutton's Green Windsor. *Climbing French:* Sutton's Earliest of All, Tender and True, Epicure. *Dwarf:* Sutton's Superlative, Canadian Wonder, Ne Plus Ultra, Negro. *Runner:* Sutton's Prizewinner, Mammoth White, Best of All, Scarlet.

BEETROOT. Sutton's Blood Red, Cheltenham Green Top, Dell's Dark Red, Dell's Black.

BROCCOLI. *First Division* (sow in April and May for cutting in September, October, and November): Michaelmas White, Veitch's Self-protecting, Walcheren, White Sprouting. *Second Division* (sow in May and June for cutting in the following January and February): Early White, Penzance Early White, Winter Mammoth, Snow's Winter White. *Third Division* (sow in March and April for cutting in March and April the following year): Perfection, Purple Sprouting, Leamington, Knight's Protecting. *Fourth Division* (sow in May and June for cutting in May and June the following year): Late Queen, Sutton's Latest of All, Methven's June.

BRUSSELS SPROUTS: Sutton's Exhibition, Daniel's Colossal, Dalkeith, Imported.

CABBAGE. *First Division* (for spring sowing): Daniel's Defiance, Enfield Market, Improved Nonpareil, Rosette Colewort, Christmas Drumhead, Winningstadt. *Second Division* (for August sowing): Ellam's Early Dwarf, Offenham, Sutton's Harbinger. *Savoy:* Sutton's Earliest of All, Dwarf Ulm, Tom Thumb, Ormskirk. *Pickling:* Large Blood Red, Giant Red Drumhead.

CARROT. *Stump-rooted Varieties:* New Early Forcing Horn, Early French Nantes, Early Scarlet Horn. *Long Varieties:* Altrincham, Red St. Valery, Long Red Surrey, Sutton's New Red Intermediate, Sutton's Scarlet Intermediate.

CAULIFLOWER: Veitch's Autumn Giant, Walcheren, King of Cauliflowers, Early London White, Eclipse, Snowball.

CELERY. *White Varieties:* Sandringham Dwarf, Sutton's White Gem, Daniel's Giant White, Silver Plume. *Red Varieties:* Standard Bearer, Leicester Red, Laing's Mammoth Red, Sutton's Dwarf Red.

CUCUMBERS. *Frame Varieties:* Lord Roberts, Improved Telegraph, Tender and True, Lockie's Perfection, Rochford's Market, Duke of Edinburgh. *Ridge or Open-air Varieties:* Stockwood, Japanese Climbing, Sutton's Long Green, Daniel's Perfection Ridge. *Pickling Varieties:* Short's Prickly or Gherkin, Prolific Pickling.

KALE OR BORECOLE: Cottagers, Asparagus, Dwarf Green Curled, Drumhead, Improved Hearting, Sutton's Kale (variegated).

LEEKS: Ayton's Castle Giant, Lyon, Musselburgh, Broad Flag or London Flag.

LETTUCE. *Cabbage Varieties:* Marvel, Sutton's Improved Tom Thumb, Drumhead, Stanstead Park, Hammersmith. *Cos or Upright-growing Varieties:* Mammoth White, Paris White, Paris Green, Little Gem, Giant.

ONION *Spring Sowing:* Ailsa Craig, Up-to-date, Rousham Park Hero, Cranston's Excelsior, Brown Spanish, Bedfordshire Champion. *Autumn Sowing:* Giant Rocca, Lemon Rocca, Tripoli Red Italian, Tripoli White Italian. *Pickling Varieties:* Silver Skin, White Queen, Early White Gem.

PARSNIPS: Hollow Crown, Student, Guernsey or Jersey Marrow.

PEAS. *First Division* (*dwarf*): Wm. Hurst, English Wonder, Sherwood. (*Tall*): Gradus, Thos. Laxton, Bountiful. *Second Division* (*dwarf*): Stratagem, The Daisy, Sutton's Dwarf Marrow. (*Tall*): Duke of York, Duke of Albany, Sutton's Prince of Peas. *Main Crop* (*dwarf*): Sutton's Invincible Marrow, Sutton's Maincrop Marrowfat, Triumph. (*Tall*): Magnum Bonum, Dr. McLean, Fillbasket. *Late Varieties* (*dwarf*): Veitch's Perfection, Queen. (*Tall*): Ne Plus Ultra, Autocrat.

POTATOES. *First Early Varieties:* Veitch's Ashleaf, Myatt's Ashleaf, Eclipse, Sir John Llewellyn, Early Puritan. *Second Early Varieties:* Beauty of Hebron, Early Rose, British Queen, Royal Kidney, Epicure. *Main Crop or Late Varieties:* King Edward VII., Scottish Triumph, The Factor, Up-to-date, Warrior, Windsor Castle.

RADISH. *Oval or Olive-shaped Varieties:* French Breakfast, Olive White, Sutton's Gem. *Turnip-shaped Varieties:* Early Scarlet, Early White, Sutton's Earliest of All. *Long Varieties:* Long Scarlet, Wood's Frame, Long White. *Winter Varieties:* Chinese Rose-coloured, Black Spanish.

SPINACH. Long Standing Round, Sutton's Long Standing Prickly, New Zealand, Perpetual or Spinach Beet.

TOMATOES. *Red Varieties:* Sunrise, Early Ruby, Frogmore Selected, Sutton's Open-air, Laxton's Open-air, Daniel's Open-air, Sutton's Main Crop for Open air. *Yellow Varieties:* Golden Eagle, Large Yellow, Sutton's Golden Queen (all open-air varieties), and Daniel's Golden Beauty and Sutton's Golden Nugget, which are hothouse varieties.

VEGETABLE MARROW: Pen-y-Byd, Custard-shaped Marrow, Green Bush, Moore's Cream, Long White-ribbed.

RHUBARB: Champagne, Early Scarlet, Myatt's Victoria, Daw's Champion, Myatt's Linnæus.

HERBS. There is always a demand for the following herbs: Balm, Basil, Chives, Fennel, Horehound, Peppermint, Rue, Winter Savory, Summer Savory, Tarragon, Hyssop, Lavender, Mint, Marjoram, Parsley, Pennyroyal, Sage, Common Thyme, Lemon Thyme.

Theories of Dyeing. Characteristics of Textile Fibres. Mordants and Fixing Agents. Natural Dyestuffs.

TEXTILE DYEING

FORMERLY most manuals for dyers were simply recipe-books. In the days when about twenty natural dyestuffs formed his complete store-house of colour, the practical dyer recorded his results from day to day, together with patterns of the actual work. A recipe, *together with the pattern*, is still interesting and useful, but, as a rule, the dyer is now able to work without specific instructions, except as to the percentage of colour to be used. If he is given a direct cotton colour or a sulphur colour or an acid wool dyestuff, for instance, he knows that a general method is applicable in each case. Recipes without patterns are therefore of little interest to him. Where one is given in this course it is merely as an illustration, and the writer has in every case seen the pattern.

The Theory of Dyeing. Volumes have been written in the endeavour to explain how it happens that a textile fibre can be permanently dyed with a soluble colour, and no solution of the problem that will meet all cases has yet been discovered. The mechanical theory is that the dyestuff is deposited and firmly held in the pores of the fibre; the chemical theory is that there is an actual chemical reaction between the mordant or dyestuff and the fibre. In some cases one or the other theory can be satisfactorily proved; in others both theories seem to fail. Until the knowledge of the chemistry of the textile fibres, and especially of cellulose, is greatly improved, the problem will remain unsolved. We have to be satisfied with knowing that we can give yarn or cloth a more or less permanent colour without knowing why.

The Textile Fibres. From the point of view of the dyer, the practical way is to divide the textile fibres simply into animal and vegetable fibres. The types of these classes are cotton and wool, by far the most important textiles, and the differences of their behaviour towards reagents are characteristic of the animal and vegetable fibres generally, and govern their treatment in the dyehouse. Wool is destroyed by moderately concentrated alkalies, but resistant to dilute acids. Cotton is not injured by moderately concentrated alkalies, but is carbonised by mineral acids, and even rather dilute acids have an injurious effect upon it. The two fibres behave very differently to tannic acid. Cotton has a strong affinity for it, which fact is taken much advantage of in dyeing, whereas wool can be made to absorb only a trifling percentage of it, and its presence on the fibre actually prevents the wool from taking the dye. On the other hand, wool has a strong affinity for many classes of dyes; it has a powerful decomposing effect upon metallic mordants, and readily retains the oxides. Cotton is very inert, and it is comparatively recently that a class of artificial dyestuffs has been discovered which will dye it without the intervention of mordants. Wool, therefore, with certain limitations, is easier to dye than cotton. Silk, in some ways, is in a class by itself. It may be looked upon as animalised vegetable fibre, but in its general behaviour to reagents it strongly resembles wool.

Vegetable Fibres. Vegetable fibres are divided into two classes—seed hairs and bast fibres. Cotton is the only textile of importance in the first category, although many attempts have been made to utilise the fibrous growth on other seeds. Kapok, also a seed hair intended to waft the seed on the wind for the propagation of the plant, has lately come into the market. It is very light and elastic, and remarkably waterproof. Unlike cotton, it cannot be bleached with hypochlorites, but is successfully treated with peroxide and perborates, and is dyed with the same classes of dyestuff as cotton.

The bast fibres are obtained from the stem of plants, as in the case of flax and jute, or from the leaves, as in the case of ramie. In cotton, each fibre is a single cell, whereas bast is composed of bundles of cells. The differences between the vegetable fibres are mainly of structure, and concern those charged with the preparative processes rather than the dyer, who, nevertheless, is obliged to modify his treatment more or less according to the particular fibre with which he is dealing. The principal constituent of all vegetable fibre is cellulose. Cotton is almost pure cellulose, linen somewhat less pure, and all the other fibres have much more of what, from the point of view of the dyer, may be looked upon as natural impurities.

Cotton. The fibre is picked by hand and ginned by machinery. Both these operations have an effect on the subsequent dyeing operations. If the cotton is not ripe, it will dye unevenly; imperfect ginning will cause it to be full of dust, seed particles, and leaf. Leaf and seed particles are very tenacious, and may appear in the yarn or even in the cloth as black spots. In this case the oil in the seed will give trouble, and cause spotty dyeing.

Nature of Cotton. Apart from these impurities, which should not be present, cotton is composed of cellulose, water, and about 5 per cent. of constituent impurities, consisting of pectic acid, colouring matter, wax, and fatty and albuminous matters. The amount of colouring matter varies greatly; it is almost absent in Sea Island and white Egyptian, and largest in brown Egyptian. In this cotton, and in the tawny fibres of India, the fact has to be taken into account by the dyer that he is dealing with unbleached goods. The wax, together with a very delicate cuticle, which is not cellulose, serves as a sort of waterproofing to the fibre. This is the reason why the dyer, dealing with unbleached goods, is obliged to scour or wet out the cotton before entering it into the dye-bath. The fatty matter in the fibre is identical with the oil in the seed, and also requires to be removed. The influence of this wax and fat can be noted if grey cloth is steeped in cold water; it will be found that a considerable time elapses before it is wetted out. The pectic acid is an amorphous

substance resembling a gum, insoluble in cold water, but readily soluble in hot.

Bleaching, therefore, in which process alkalies are used and form soaps with the fatty matters, removes these impurities and leaves almost pure cellulose, the albuminous matter being in such small quantity as to be negligible.

This general inertness, although it is the cause of the want of affinity for colouring matter, is of valuable assistance to the dyer, inasmuch as it enables cotton to stand all the various processes through which he has to put it. Cellulose, moreover, is hygroscopic, and the moisture taken up from the air renders the fibre soft and elastic.

Mercerised Cotton. John Mercer, a Lancashire calico-printer, in 1844 discovered that cotton treated with caustic soda of a certain strength shrinks, gains strength, and acquires greater affinity for colouring matters. He took advantage of the shrinkage to produce crape effects by printing cloth in patterns of stripes with caustic soda lye, allowing it to dry, and steaming the fabric. The printed parts contract and remain smooth, dragging the unprinted parts with them, which thus become crinkled. This is one of the methods of producing the cotton crépons which are on the market.

Lustre-Mercerisation. After Mercer's time it was discovered that if a fine cotton yarn is held in tension during mercerisation, and prevented from shrinking by washing out and neutralising the lye with acid, the fine staple takes a silky gloss. The chief interest in the process today lies in this lustre-mercerisation, by which cotton is given the appearance of silk; and it is necessary for the dyer to understand the properties the cotton has acquired and the new conditions under which he must work. Generally speaking, all classes of dyestuffs ordinarily used for cotton are available, but 25 to 35 per cent. less dyestuff is required to dye to the same depth of shade, and the colour goes on much more quickly than in the case of unmercerised cotton. This tends to uneven dyeing, and the remedy is long baths—this is, with plenty of water—the employment of colours which exhaust slowly, a decreased addition to the bath of Glauber's salt, and more soda, soap, or other ingredients which retard the action of the colouring matter. In the case of dark shades, the bath, of course, must not be too long. Another point the dyer must take into consideration is that the manner of dyeing must not injure the lustre of the goods. For this reason the direct cotton dyes are largely employed on mercerised material. In union goods, when mercerised and dyed cotton is used, the dye is more liable to bleed on to the wool than ordinary cotton, and a class of dyestuffs has been introduced to remedy this.

Apart from lustring, Mercer's original idea of using caustic soda to economise dyestuff has found a limited use. It was quickly discovered that even comparatively weak lyes, not capable of contracting the cloth, would save dyestuff, and that certain wool dyes could be used on mercerised cotton. With both the natural and the artificial colours there is always an economy of dyestuff, and sometimes a simplification of the process, as in the case of several basic dyes, which may be used without a mordant. It is very necessary, therefore, that the dyer should study mercerised cotton from every point of view.

Linen. Being a bast fibre, flax is much more difficult to prepare for the spinner than cotton; and the most important operation is retting, in which process the flax is steeped in cold or hot water to remove the adhesive substances which bind the fibres to each other and to the woody portion of the stem. The method of retting is of importance to the dyer, inasmuch as it influences the colour of the product as he receives it. The fibre should then be snowy white and lustrous.

Its chemical composition is very similar to cotton, but it contains more pectic acid and other impurities, from which it is freed on bleaching, as in the case of cotton. It absorbs about the same amount of moisture, but is a better conductor of heat and is less elastic. It is more affected by caustic alkalies and bleaching agents; and although it is cellulose, and the methods employed are much the same as in cotton dyeing, it is more difficult to deal with. Even unbleached linen, however, can be readily dyed with substantive cotton colours, by boiling twice with 5 per cent. soda and rinsing well. It has some affinity for the basic dyes, as it contains a small amount of tannin. The fibre, as it comes to the dyer, contains woody and waxy impurities, varying according to the nature and thoroughness of the preparatory operations, and also cellulose converted by the pectic acid into pecto-cellulose.

The introduction of direct cotton dyestuffs, however, greatly simplified the dyeing of linen, and they are very largely employed.

Jute. The preparation of the fibre from the plant is similar to the processes used in the case of flax, but simpler, and the product is freer from woody impurities. The physical structure is the main difficulty of the dyer, and the dyed jute often shows an absolutely untouched centre if the fibre is cut across. This is of little moment, however, in the ordinary uses of jute.

It is best bleached by the successive action of permanganate of potash and sulphuric acid, but the bleach does not last. Treated as in cotton bleaching, but with weaker lyes, an imperfect but more stable bleach is obtained. The dyer has to put his best work in when the jute fibre is intended for use as a binding thread in carpet weaving, or for cheap classes of upholstery.

Hemp. A large number of bast fibres come on to the market under the name of hemp. It is fairly successfully bleached in the Dundee district by special processes, but rapidly turns brown and is tendered to some extent in the process. It is rarely dyed, but when this is required the substantive dyes are used as for cotton.

Ramie. China grass, rhea, or ramie is nearly pure cellulose, and consequently can easily be bleached. It can be dyed like cotton, but care must be taken to preserve the lustre. In light shades, obtained with the substantive colours in lukewarm baths, it has been used for curtain laces and napkins. It has also been used for upholstery.

Artificial Silk. Several varieties of this are on the market, but they are now all obtained from solutions of cellulose. They are dyed like ordinary boiled-off silk, but at lower temperatures.

The Animal Fibres. The animal fibres have nothing in common with the vegetable fibres in chemical composition, and are treated in a totally different manner in bleaching and, as a rule, in dyeing. They are nitrogenous substances, and frequently contain sulphur. The great difference between the animal and vegetable fibres is emphasised by a rough test very frequently used by dyers. Take a warp thread of a union cloth and apply a lighted match to it. It burns with a quick,

bright flame, and without smell—it is vegetable fibre. Take a weft thread and hold the light to it. It shrivels up in a brownish bead, and gives off the smell of burning horn—it is an animal fibre. The results, of course, will be reversed if the warp is wool and the weft cotton.

The chemical composition of wool fibre itself, when freed from impurities, closely resembles that of horn. It consists of carbon, hydrogen, oxygen, nitrogen, and sulphur, and the presence of this last element distinguishes it from silk.

The sulphur may cause trouble to the dyer. If the water contain lead, dull shades are produced in a neutral or alkaline bath, but this may be corrected by adding sulphuric acid, or in some cases alum. If the wool comes into contact with lead, copper, or tin, stains result, owing to the formation of the sulphides of these metals. Mordanting with a tin salt has the same result. If necessary, the sulphur may be almost removed by steeping the wool in milk of lime, washing in water, then in weak sulphuric acid, and again in water, repeating the operation several times.

Effects of Acids on Wool. Solutions of hydrochloric and sulphuric acids have little effect on the fibre except that they make it feel harsher. They are used in the dye-bath in wool dyeing, and as they are more energetic in their action on cotton they are also used to remove this fibre from rags or shoddy. One process is to steep the shoddy in dilute sulphuric acid, squeeze out, and dry in a stove at about 225° F. The cotton is carbonised and disintegrated, and can be beaten out of the goods.

Concentrated mineral acids destroy wool. Dilute boiling nitric acid is used to take out the colour from goods already dyed, as, for instance, in "stripping" garments for re-dyeing or ir. correcting dyehouse mistakes. Sulphurous acid is used as a bleaching agent, as wool would be destroyed in the process applied to cotton, and must be thoroughly removed by steeping it in very weak solutions of chloride of lime and washing well. Otherwise uneven dyeing will result, especially with light colours, which may even be destroyed by the sulphur dioxide retained in the fibre.

An excess of chlorine destroys wool, but when the fibre is submitted to the slight action of chlorine or of hypochlorite it is said to be "chlorinated," and has acquired some very valuable properties. It has a yellowish tint and a harsher feel, but it has lost most of its power of felting, and therefore the process is used to prevent the shrinking of woollen hosiery and clothing. It has also acquired a greater affinity for colouring matter. This is taken advantage of by the muslin delaine printer very extensively, and also to some extent by the wool dyer, who, for instance, can produce two-colour effects on all wool goods by chloring the warp before weaving, and leaving the weft untreated. The warp then takes up a much deeper colour in the dye-bath.

Effect of Alkalies on Wool. The action of alkalies on wool is very peculiar. While comparatively weak lye at an ordinary temperature disintegrates the fibre more or less rapidly, a short immersion in caustic soda of 82° Tw. at a low temperature, say 50° F., produces an effect analogous to mercerisation. The fibre takes a soft silk feel and scroop, and a greater affinity for colouring matters. The economy of dyestuff effected has never been sufficiently experimented upon, but two-colour effects have been produced in the piece by using "mercerised" and "unmercerised" wool after the manner of chlorinated and untreated fibres. The treated wool is also freed from sulphur to a large extent.

Wool, unlike cotton, has a positive action on metallic mordants, readily decomposing them in hot solutions and retaining their oxides in the fibre. It has also a strong direct attraction for several classes of colouring matters. Its porosity also enables it to be readily treated. This general activity makes the dyeing of wool comparatively easy, but on the other hand it has the drawback of being the frequent cause of uneven dyeing. In most cases the care of the dyer must be to moderate the action of his baths, and to regulate his work so that one portion of his goods does not absorb an unfair share of the dye.

Wool from a diseased animal dyes badly, and from the dead sheep much worse still. "Dead fibres" which have been pulled out before the sheep was sheared take the colour badly, and "kemps"—smooth, white, almost scaleless fibres, met with in coarse wools—also take less colour and may produce spotty dyeing. They are usually combed out, however, in the preparatory processes.

Silk. Raw silk consists of a double fibre cemented with a layer of silk glue. When "boiled off" the fibres are separated, and, losing the yellow of the enveloping glue, are almost white and lustrous. They differ from vegetable fibres and from wool by being devoid of cellular structure. Silk resembles wool in some respects, but it is distinguished from it chemically by the absence of sulphur. It is very hygroscopic, and will absorb 30 per cent. of moisture without feeling damp. It is very elastic and strong, and has a high lustre.

A very distinctive property is the peculiar crisp, rustling sound it emits when it is squeezed in the hand. This is known as the *scroop*, and is imitated by chemical means in mercerised cotton. What the French call the *frou-frou* is a valued property in ladies' dress material, and the retention of it has to be carefully ensured in the dyeing operations. Raw silk has no scroop, the property being imparted to it in an acid bath after boiling off. It can be imparted to it after dyeing, and this is usually done in a bath containing oil and acid. Silk is a bad conductor of electricity, and therefore becomes electrified by friction; this is overcome by keeping the air moist in rooms where it is worked.

Silk decomposes metallic mordants as readily as wool. Potassium bichromate injures the fibre, and dilute solutions of bleaching powder chlorinate it like wool, increasing its affinity for colouring, but to a less extent. It is very easily tendered, even sodium carbonate affecting it in warm solutions, and this is a point that the dyer must bear in mind. It behaves like wool to colouring matters, and can be easily dyed direct with several classes of them, and its affinity for the basic dyes is even greater than wool.

Mordants and other Chemicals. The dyer uses a large number of drugs in preparing his material for dyeing—such as mordants, as fixing agents and assistants for the mordant, as levelling agents, and as solvents for dyestuffs. The method of preparation and minute description of these substances belong to the domain of general chemistry, and very voluminous works are devoted to the subject. In this course we must consider them purely from the point of view of the dyer.

The French dyers use the term *mordant* (biting) because they thought that the mordants simply prepared the way for dyeing by biting into the fibre

and opening the pores. It has long been known that they act by forming a coloured lake, closely combined with the fibre, either by fixing the dyestuff or by actually forming an essential element in the colour. The mordant must not affect the properties of the fibre, and must penetrate it thoroughly; otherwise, if it is only superficially attached, the colour will not be fast to rubbing.

Aluminium Salts. Aluminium mordants are used on all the fibres. Alum is the double sulphate of aluminium and potassium or ammonium. Dyers prefer commercial alum to the sulphate, but they are both used as mild acids in dyeing acid colours on wool and as mordants on cotton, but not to a large extent, as very little alumina is fixed on the fibre. On wool and on silk the sulphate is the principal aluminium mordant. The other aluminium mordants are principally used in textile printing.

Iron Salts. A large number of ferrous and ferric salts are used by the dyer.

Ferrous sulphate, usually termed *copperas* or *green vitriol,* is employed in the manner described below under the head of "Natural Dyestuffs," and for darkening the colours obtained with some of the basic coal-tar colours.

Pyrolignite of iron, or *black liquor,* is ferrous acetate containing a little ferric acetate, and is used principally by the cotton printer and in black-dyeing silk. *Ferric sulphate,* very misleadingly termed *nitrate of iron,* is used very largely in black-silk dyeing and for cotton. The real *ferric nitrate* finds a limited use for buff shades on cotton.

Chromium Mordants. *Bichromate of potash* or *soda,* often simply called "bichrome," is an everyday mordant for wool. Commercial sodium bichromate is less pure than the corresponding potassium salt, but is cheaper, and is usually employed. A very small proportion of bichromate has great mordanting power—in fact, the danger lies in "over-chroming" the wool. *Chromium fluoride* is also used, generally with oxalic acid as an assistant. On silk, *basic chromium chloride* is used, fixed with silicate of soda. The cotton dyer does not use chromium mordants very largely, but uses bichrome to make certain colours faster to washing.

Khaki can be dyed on cotton with metallic oxides. The word itself means "earthy," and khaki, it is said, has been a military colour from the days of Alexander the Great. Our soldiers in India, in cases of sudden outbreak on the frontier, dyed their white cotton twills in fresh cow-dung. The Boer War brought khaki very much to the front; and a long range of drab shades produced with natural and artificial dyes are now described under the name. The military authorities are very exacting as to the properties of fastness of the dye.

Tin Mordants. The stannic salts are much used for the vegetable fibres, especially with the natural dyestuffs. The wool dyer principally uses *stannous chloride,* under the name of *tin salts* or *tin crystals. Tin spirit*—that is to say, tin dissolved in acids—is hardly used now. *Stannous nitrate* is employed in dyeing cochineal-red on wool.

Copper Mordants. The copper salts are used principally as oxidising agents, but *copper sulphate,* known as "bluestone" or "blue vitriol," is employed to some extent as a mordant in wool dyeing, and cotton dyed with some of the direct cotton colours is after-treated with copper sulphate to make the shade better able to resist washing.

Lead Mordants. *Acetate of lead,* known as "sugar of lead," and *nitrate of lead* are used by the cotton dyer in producing the once favourite colours known as "chrome orange" and "chrome yellow." The cotton is mordanted with the salt and passed through milk of lime, and then through a bath of bichromate of potash.

A large number of other metals have been used as mordants experimentally, and some of them have found a use, but principally in textile printing.

The Tannins. A large number of vegetable substances contain tannic acid, or an organic acid resembling it in chemical constitution and properties. They are capable of converting hide into leather, and their astringent properties make them useful in medicines as styptics. They are used also in the production of inks, and in the manufacture of a class of dyestuffs. Some of them, notably cutch and gambier, contain colouring matter sufficient for use as a dye, and are natural combinations of mordant and colouring matter.

The principal value of the tannins to the dyer lies in the fact that, whereas vegetable fibre has little affinity for dyestuffs, it greedily absorbs tannic acid, which is capable of forming insoluble compounds in the fibre in combination with the basic dyestuffs. In silk dyeing the tannins are principally employed as weighting material, and as both dye and weighting material for black silk. In wool dyeing they find a very limited use. The fibre has little affinity for tannin, and the small quantity that it absorbs is a resistant to some dyestuffs. Before the days of the artificial dyes, many of the tannins were used for the sake of the colouring matter they contain. Tanner's bark, gall nuts, chestnut husks, and sumach were all employed as actual dyestuffs in English dyehouses, and country people used the bark of the birch and willow and other trees. Practically, cutch and gambier are now the only tannins used as dyes; and the value of a tannin to the cotton and linen dyer largely depends upon the *absence* of colouring matter.

Tannic Acid. This is prepared for the dyer from Chinese and Japanese galls, and comes on to the market as pale yellow powder and as crystals. The commercial acid can be freed from its colouring matter by shaking it up with ether and allowing it to settle. The lower layer then is almost colourless tannic acid. It was considered necessary to use this tannin exclusively for delicate shades, but colourless extracts of sumach are now on the market, and are less expensive. Tannic acid, however, is the ordinary tannin matter in the dyehouse.

Oak galls are produced by the puncture of a female wasp, and the richest in tannic acid come from Aleppo. Chinese and Japanese galls are produced by the puncture of an insect on the trees of the *Rhus* family. These are not much used directly in dyeing, but for the production of tannic acid.

Knoppern are produced by the insect puncture of the unripe acorns of an oak grown principally in Germany and Austria. They are very rich in tannin, and the Germans use them in ink-making.

Sumach and other Tannin Sources. Sumach is the leaves of certain species of rhus which are ground up for sale. Sicilian sumach is the best, but it is very often largely adulterated, notably with the leaves of the lentisk. Sumach should contain 15 per cent. to 20 per cent. of tannin. It is a very hardy shrub, and flourishes in the South of England. As there is a market for guaranteed pure sumach, it might be profitable to grow it on waste land in England. It is very largely used in cotton dyeing, as the slight amount of red colouring matter it contains is not a disadvantage for many uses.

Myrobalans, sometimes written *myrobolams,* are the dried, plum-like fruit of several species of trees,

and are obtained chiefly from the *Terminalia* of India. The stones contain little tannin; and as they may amount to 50 per cent. of the weight of the myrobalans, this has to be taken into consideration in sampling. Myrobalans are cheaper than sumach and richer in tannin, but they contain a yellow-brown colouring matter which unfits them for light-shade dyeing. They are largely used in dyeing dark shades and black on cotton and silk.

Valonia is the acorn cap of several species of oak grown in the Levant. It contains a dirty yellow colouring matter, and is little used by the dyer, except occasionally in silk dyeing.

Trillo is a tannin consisting of the scales of the acorn caps. *Divi-divi* is the pod of a shrub grown in the West Indies. It is used in dyeing black.

Canaigre, the dried root of a specie of dock, has been suggested as a substitute for sumach. It is very rich in tannin. The English dock was experimented upon, but the attempt to cultivate it as a tannin does not seem to have been successful. A large number of other tannins, such as quebracho and algarobilla, are used by the leather tanner.

Oils. Olive and castor oil are converted into "Turkey-red oil," or sulphated oil, by treatment with sulphuric acid. Castor oil is principally used in England. It is decomposed with concentrated sulphuric acid, and the mixture of fatty acids resulting is washed with common salt, and neutralised with caustic soda. It must be perfectly neutralised or slightly alkaline, and is then soluble in distilled water to a clear solution. It is used as a mordant for basic colours in some cases, but the shades it gives, although brighter, are not so fast to washing as those got on a tannin mordant. It is indispensable in fixing mordants for alizarine dyeing. In the old process of Turkey-red dyeing with madder, rancid olive oil was used. Lately Turkey-red oil preparations in the convenient form of soaps have come into use, *Monopol soap*, *Tetrapol*, and the *Polysulfol oils and soap* among others, and find many uses in dyeing.

Fixing Agents and Assistants for Mordants. The mordants require to be decomposed, and the oxide, which is the actual mordanting agent, must be firmly fixed on the fibre. Wool is capable of decomposing mordants unaided, but, as in chrome mordanting, not without some injury to the fibre. Fixing agents, or assistants, are therefore added to the bath.

Caustic Soda. This is used sometimes as a solvent for alumina and stannic oxide. It is used in the production of *manganese brown*, also called *manganese bronze or bistre*, formed by fixing manganic oxide upon cotton. This colour is very fast to light and washing, and is now also obtained by steeping the cotton in a solution of manganous chloride, drying in the hot flue, and passing through a warm solution of potassium permanganate. Caustic soda also fixes ferrous or ferric oxide on the fibre, producing in this way two other mineral colours, known as *iron-buff* and *nankin-yellow*. It is very largely used in mercerisation, and at a certain degree of concentration has the effect of increasing the affinity of the cotton fibre for dyes.

Sodium Phosphate. This is a useful assistant with aluminium mordants.

Sodium carbonate finds many uses in dyeing. The *soda crystals* are the familiar "washing soda" of the household. In a crude, calcined form, the carbonate is called *soda ash*. It is largely used for softening water, for neutralising acids, and for fixing ferric and chromic oxides on cotton.

Sodium sulphate or *Glauber's salts*, and *sodium chloride* or *common salt*, may be considered together, as the dyer uses them for the same purpose. Neutral Glauber's salts should be in clear, transparent crystals, containing no iron. Calcined Glauber's salt is made by driving off the water of crystallisation, and very much less of this is needed in the dye-bath. Common salt and Glauber's salt are used in the dye-bath to aid the colour to go on the fibre.

They are often used in large quantities, and raise very considerably the boiling-point of the liquor, which has a beneficent action in some cases. In woollen dyeing they render the colour less soluble, so that it is dissolved more gradually, and goes on the wool more evenly. Glauber's salt or common salt is very frequently the only addition to the dye-stuff in dyeing with the direct cotton colours, especially in dyeing mixtures of wool and cotton, in which case the bath must be neutral.

Sodium bisulphate, or acid sodium sulphate, is used as a milder substitute for a mixture of Glauber's salt, and sulphuric acid. It is sometimes called *tartar substitute*.

Sodium sulphide is used as a solvent, or, rather, reducing agent, for the sulphur colours which are insoluble in water alone.

Sodium phosphate is sometimes used in Turkey-red dyeing as an assistant for aluminium mordants.

Ammonia is used for neutralising acids, and in all cases where the wool dyer needs a weak alkali. It is used for neutralising Turkey-red oil, as its volatility allows it to be readily driven off.

Lant—that is, stale urine—is the mildest form of ammonia.

Ammonium carbonate is used for scouring wool, and is one of the best agents for fixing alumina on cotton.

Tartar emetic is largely used for fixing tannic acid in dyeing cotton with basics. It is *antimony potassium tartrate*, but is invariably called tartar emetic in the dyehouse. Its expense has caused many substitutes to be offered. *Antimony potassium oxalate*, known as *binoxalate of potash*, which is cheaper, may be used in some cases. A double salt—*antimony fluoride and sulphate*—has been sold for the purpose, and there are various patented preparations on the market.

Potassium ferrocyanide, known as *yellow prussiate of potash*, and *potassium ferricyanide* (*red prussiate of potash*) have been used as mordants instead of tannic acid. The yellow prussiate is used in dyeing aniline black. *Prussian blue* is perhaps the most important of the mineral colours. It is produced on cotton or silk by dyeing the material iron-buff [see Caustic Soda above], and passing it through a weakly acid bath of yellow prussiate, and on wool by dyeing with yellow prussiate in a strongly acid bath at the boiling-point.

Argol, or *argols*, is the crude cream of tartar in the lees of the wine vat, and is red or white according to the colour of the grape. It is added to mordants, especially to alum, the resulting double salt giving up more alumina to the fibre. The decomposition of the mordant with argol produces tartaric acid, which does not affect the dye-bath, whereas if sulphuric acid were used to decompose the mordant, and remained in the fibre in the dye-bath, it might injure both the colour and the material.

Calcium Salts. When *quicklime* is slaked, *calcium hydrate* is produced. Water dissolves very little of this, and the *lime-water* holds particles in suspension. This is known as *milk of lime*. It is largely used in fixing iron mordants and in bleaching. *Carbonate of lime*, or *chalk*, is used in fixing alumina

in alizarine dyeing, as lime in some form or other must be in the dye-bath. *Acetate of lime* is very frequently employed for this purpose, and also in dyeing with several of the natural dyestuffs. *Chloride of lime* (bleaching powder) is a misnomer. It is really a hypochlorite.

Acids. The mineral and organic acids are extensively used as solvents, neutralising agents, reducing agents for mordants, and for many other purposes.

Soap is very largely used by the dyer. It is a necessary assistant in many dye-baths, and the ordinary way of dyeing silk is to use a soap-bath plain, or "broken" with acid. It is a very useful plan to "soap" dyed goods in order to brighten the colours. The dyer needs soap of a good quality, and, as a rule, neutral.

Quillaia, variously known as quillaia bark, Panama bark or wood, and soap bark, is the bark of several species of Rosaceæ, growing in Chile, Peru, and Brazil. It contains saponine, which has great lathering and cleansing power. The wool dyer uses it where soap would be inadmissible, and it has no harmful effect on the most delicate dyes.

Natural Dyestuffs. Local uses are made of a large number of natural dyestuffs even in the British Isles, but it is not practicable to consider any colouring matters of this class that are not ordinary articles of commerce. The natural dyestuffs are drawn mainly from the vegetable kingdom; a very small group are of animal origin. The coloured oxides of many metals can be fixed on the fibre, but these are used as mordants, and the few mineral colours are of little importance in dyeing, and have been mentioned in describing the salts which produce them. Bancroft, whose "Philosophy of the Permanent Colours" was published in 1794, divided the natural dyestuffs into two groups—"substantive," those with which no mordant is necessary; and "adjective," those that could not be fixed on the fibre without a mordant. These terms are now used in connection with the artificial colours. Even before the days of synthetic colours the number of natural dyes in general use was very limited. Apart from the mineral colours, logwood, madder, peachwood, camwood, barwood, sanderswood, cochineal, indigo, old fustic, weld, quercitron bark, cutch and gambier, turmeric, sumach, and gall nuts almost exhaust the list. They were generally used in combination, and thus a large range of tint was obtainable.

Indigo. Indigo, unfortunately, is decreasing in importance year by year. It was long looked upon as the queen of dyestuffs. Indigotin is the blue-colouring principle in indigo, and artificial indigotin has put the natural dyestuff more and more in the background. It is probable, nevertheless, that indigo will always find limited uses. The indigofera are very numerous, but the plants cultivated principally are I. anil (whence the word "aniline"), I. argentea, I. disperma, and I. tinctoria. The last of these is most extensively cultivated. The colouring matter of the woad plant, *Isatis tinctoria*, is identical with indigo, but the dyer used woad only as a ferment in the indigo vat.

Indigo is absolutely insoluble in water, but on treatment with an alkali and a reducing agent it is converted into indigo-white, which dissolves in the lye. When cloth is steeped in the vat thus made, and exposed to the air or passed through an oxidising agent, the indigo-blue forms on the fibre. In the woad vat the indigo is reduced by taking up the hydrogen produced by fermentation, and indigo-white thus obtained is dissolved by slaked lime. Madder is used in this vat, which is employed principally for heavy woollens, and requires skill and experience. The zinc vat is largely used in England for cotton, and is perhaps the simplest of the indigo vats. Indigo, zinc, lime, and sometimes iron filings are added to the water, which is kept stirred for eighteen hours, and then left to settle. The zinc decomposes the water, and the hydrogen reduces the indigo as in the case of the fermentation vat. The iron filings form a rough surface, aiding the evolution of the hydrogen, and form a galvanic couple with the zinc. A large number of vats are in use, each having advantages for a particular purpose. They all depend on the same principle of the reduction (or hydrogenation) of the insoluble indigo-blue to the soluble indigo-white:

$$\underset{\text{Indigotin}}{C_{16}H_{10}N_2O_2} + \underset{\text{Hydrogen}}{2H} = \underset{\text{Indigo-white}}{C_{16}H_{12}N_2O_2}$$

The indigo-white is fixed on the fibre, and on reoxidation is reconverted into the insoluble blue:

$$\underset{\text{Indigo-white}}{C_{16}H_{12}N_2O_2} + \underset{\text{Oxygen}}{O} = \underset{\text{Indigo-blue}}{C_{16}H_{10}N_2O_2} + \underset{\text{Water}}{H_2O}$$

The blue fixed on the fibre cannot be washed off again, and it is easy to see from this the great advantages and the one fault of indigo. It is very fast to light and washing, but the outer part of a fabric will lose some of its colour by rubbing. Indigo contains red, and generally some brown and yellow colouring matters in addition to the blue; also a body which becomes a sugary substance like gluten. These play a part in dyeing, but their exact nature is not known. They give indigo, however, properties that are absent in indigotin or artificial indigo.

Principal Indigo Vats. Some of the principal vats are as follows:

The *copperas vat* is not so simple as the zinc vat, but it is cheaper, and English dyers have used it for cotton since the time of Elizabeth. The vat is "set" with indigo, copperas (ferrous sulphate), fresh slaked lime, and water. In this vat the lime is an active reagent, as well as a solvent for the indigo-white. It combines with the copperas to form ferrous hydroxide, which reduces the indigo. The lime must be in excess to provide for its use as a solvent. This vat requires experience, and it is left to the experts who know how to humour it.

The *hyposulphite or hydrosulphite vat* is a modern vat very much in favour, as it can be used for both wool and cotton. Acid hyposulphite of soda is the reducing agent, and the dyer prepares this by the action of zinc on sodium bisulphite. The hyposulphite is prepared immediately before use, and added to indigo, ground into fine powder, and slaked lime. The vat is used cold for cotton and lukewarm for wool.

In *fermentation vats* any substances such as bran, starch, or glucose which will ferment may be used, as has already been explained in the case of woad. Benoist and Collins actually made a culture of the ferment that produces hydrogen—*Desmobacterium hydrogeniferum*—and added a trifling proportion of it to a vat prepared with food for it. The advantage of it is that this can be worked at a higher temperature than other fermentation vats; therefore it is more rapid in its dyeing action and more easily worked.

In the *stannous hydrate vat*, stannous chloride with caustic soda is the reducing agent. It is said

to be simpler than the copperas vat, but is little used in England.

The different vats have an influence on the shade. The woad gives the brightest shades, and the alkaline vats are best for the dark shades required for uniforms.

It has always been necessary, in view of the high price of indigo, to recover the unspent dye from the "bottoms." The copperas vat, in particular, is not exhausted. Many devices have also been used to combine indigo with other dyes, to obtain its peculiar bloom and excellent qualities with less expense. A very usual plan is to "bottom" the goods with camwood or barwood first, and afterwards with indigo, or the indigo is "topped" with suitable artificial dyes after a light shade of indigo has been obtained in the vat. These shades are termed "woaded" colours.

Natural indigo is holding its own best in woollen dyeing in the fermentation vats. Natural indigo is more suitable than artificial indigotin for use in these vats, which leave the wool with a softer feel than the chemical vats.

The hydrosulphite vat, however, is much the simplest, and is the one ordinarily used for artificial indigo and for other highly important vat-dyes to be described later in this course.

Natural Dyestuffs. *Logwood.* This dyewood has withstood the attack of the artificial dyestuffs better than any of the natural dyes, on account of its cheapness, comparative ease of application, the beauty of its shades, and its excellent qualities of fastness to light, washing, and acids. The best quality was formerly grown in the Bay of Campeachy, and the French still call it Campeachy wood, but Jamaica logwood is now considered the best. Logwood contains a yellowish-white crystalline body known as *Hæmatoxylin*, which oxidises in the air and takes a high colour. It is then known as *hæmatin*, the actual colouring principle of the wood.

Logwood reaches England in large logs, and these are converted into chips, plentifully sprinkled with water, and exposed to the air. The temperature and state of the weather has a great influence on the wood during this process of "ageing," and it requires experience. In unskilled hands the wood may be over-oxidised and the colour lost. This has brought logwood extracts into favour, and in particular hæmatin, procurable in liquid, powder, or crystals. These are dearer, however, than the wood, which must still be used for many purposes.

Logwood is dyed in the usual manner employed for mordant colours. The material may be dyed first, and then mordanted, a method sometimes preferred by the wool dyer, but it is usually mordanted and then dyed. The one-bath method, using dye and mordant together, is sometimes used, but causes a waste of dye, and for the same reason —that is, the precipitation of the dye in the bath —the colour is liable to rub off the goods. Even when cotton or wool is first mordanted and then dyed, there is still loose colour on the fibre, and to fix this the goods are mordanted again after dyeing —a process which is called *saddening.*

Dyeing Cotton with Logwood. Logwood is used exclusively for full, bloomy blacks on cotton, rarely for greys. An iron mordant is used, fixed with tannin. The modern practice hardly differs from that followed in the days before the aniline dyes, and the following old and approved recipe is little varied from :

Full Black on 20 lb. Cotton. To a vat of cold water add 5 lb. of sumach. Enter the goods, give a few turns, and leave all night. Then pass through lime-water ; add to this 2 lb. of copperas solution and a pailful of the old sumach liquor. Enter and give six turns, wring out ; enter the lime vat again, and give two pails more lime liquor. Then scald 6 lb. of logwood and 1 lb. of fustic; add this to another vat of water, enter, and give ten turns ; lift, and sadden with a little copperas—in the same liquor—and soap.

Sumach is now used in a hot solution, and a proportionate amount of logwood and fustic extracts are employed. For the best class of goods "nitrate of iron" (ferric sulphate) or acetate of iron is used instead of the copperas. A very ordinary method with cotton cloth is to pad the goods in acetate of iron, dry, pass through lime-water, and dye in logwood extract. Another largely used process is to used sulphate of copper as the mordant. Formerly, the best purple that could be dyed was got with logwood, and this is still used occasionally.

Fast Purple on 20 lb. Cotton. Give a blue bottom in the copperas vat, then a few turns in cold water, with a little stannous chloride at 2° Tw. In another vat add 4 lb. or 5 lb. of logwood previously spent, and give eight turns.

Lavender shades are dyed in the same way, with less logwood, and light blues are dyed in the copperas vat. Chrome may be used as the mordant in black dyeing, but the result is not so good as with iron.

Dyeing Wool. As lately as 1890, Hummel asserted that "logwood is the essential basis of all good blacks on wool." The mordants are generally either copperas or chrome. The latter is now the favourite, but it makes the wool harsher than copperas, and liable to take a greenish cast if the chroming is not uniformly done.

Black. The wool is mordanted as usual with chrome—that is to say, with 3 lb. bichromate of soda and 1 lb. of sulphuric acid to 100 lb. of goods. The dyeing is done at the boil, with 50 lb. of logwood, the shade being toned as before with fustic. Where yarn has to stand milling with white yarn it is saddened as already noted. A direct black may be made by precipitating the logwood with the chrome, the lake thus obtained being dissolved with oxalic acid for use.

Wool is frequently given a light bottom in the indigo vat, and dyed either a copperas or a chrome black. These are called *woaded black.*

Blue. For 100 lb. of goods prepare a bath with 10 lb. alum, 6 lb. argol, $1\frac{1}{4}$ lb. tin crystals, $\frac{1}{4}$ lb. sulphuric acid (D.O.V.). Boil in this for two hours, then dye in a bath containing from 10 to 15 lb. logwood extract and 1 lb. soda.

A light blue is dyed by mordanting with $\frac{3}{4}$ lb. of alum and $\frac{3}{4}$ lb. of chrome per 100 lb. of goods, and dyeing with about 100 lb. of logwood raspings, boiled up in bags. A recipe for a logwood blue, resembling indigo, on 100 lb. of wool was to mordant for one hour with $\frac{1}{2}$ lb. of bichrome, 2 lb. of alum, and $\frac{1}{2}$ lb. of red argol, then dyeing with 20 lb. of logwood.

Other Colours. Logwood greens would probably not be considered satisfactory nowadays. They were dyed on a chrome and alum mordant with fustic and logwood. About three times as much fustic as logwood gave a light green, and by adding a larger proportion of logwood any shade of dark green could be obtained. Drabs were obtained by mixtures of logwood, barwood, and fustic, after-treated with copperas. By various proportions of these dyestuffs a large variety of shades were produced on a chrome mordant, light drabs to a dark brown, and greens, purples, clarets, and olives.

Dyeing Silk. Logwood is largely used for silk; exclusively for black. The silk dyer weights the silk in the operation, and as the process is long and intricate, and varies with each description of silk, it is beyond the scope of this chapter.

Cutch and Gambier. These closely allied dyestuffs are still largely used by the dyer, and will probably be able to compete with the artificial dyestuffs for many years to come. Bombay cutch, or catechu, is considered the best quality, and is obtained from the species of *Areca*. Bengal cutch, containing more tannin but less colouring matter, is obtained from species of *Acacia* and *Mimosa*. Gambier, somtimes called cube or yellow cutch, is obtained from a Batavian shrub, *Uncaria catechu*. Formerly it was thought that these dyestuffs were earthy matter, and they were called *terra Japonica*, or Japanese earth. Gambier was looked upon as merely an inferior quality of cutch, but the main differences seems to be that it is less oxidisable; and an article on the market, known as *patent cutch*, is prepared from gambier by adding oxidising agents.

Cutch and gambier have been classed as tannins, and, as a matter of fact, they contain about 60 per cent. of tannin to 8 per cent. of colouring matter. This colour puts cutch and gambier out of the question for mordanting cotton, but gambier in particular is largely used in tanning. The reactions of cutch with the various mordants is very varied, and it is used for a variety of compound shades, especially browns, drabs, and fawns, which are very permanent. The quality of the dyestuff is usually gauged by the extent of its solubility in cold water. Gambier is almost insoluble, but dissolves readily in hot water.

Dyeing Cotton with Cutch. An old recipe says: *Brown on* 20 *lb. Cotton.* Spend 6 lb. of cutch with 6 oz. of sulphate of copper in boiling water. Turn the cotton over in this bath for about fifteen minutes; enter another bath made up with bichromate of potash at the boil. Repeat the baths until the cotton is dark enough. This is nearly the modern practice, except that the cotton is allowed to lie some hours before entering into the bichrome bath. Cutch and gambier are largely used, together with other natural colouring matters and with artificial dyes, to produce compound shades.

Dyeing Wool. Wool is dyed like cotton, but cutch is not a favourite with the wool dyer, as it gives the material a harsh handle. Used, however, for light browns, there is nothing to object to in a cutch-dyed woollen or worsted. Wool is dyed much in the same way as cotton. It is worked for an hour at the boil in the cutch bath without addition, and then chromed in a fresh bath.

Even for full shades the harshness of handle can be avoided. The cutch is ground up thoroughly in cold water, and allowed to stand and settle for some time. The water is then decanted off, and the residue, which is mostly the essential colouring principle of the dyestuff—that is, catechin—dissolves in the boiling bath, and is used for wool dyeing, with an after-treatment with bichrome or sulphate of copper.

Cutch has long been used as a constituent in khaki dyeing. One fairly old method was to mordant with myrobalans and sulphate of copper, and then dye with cutch and a redwood with a little sulphate of iron, finally chroming. The shade could be varied by altering the proportion of the iron and copper salts.

Dyeing Silk. Gambier is largely used in silk dyeing, as it acts as a weighting material as well as a dye, and resists the soap-baths, which cutch does not. As long as weighted silks can find a market, gambier will be a most important weighting material to the silk dyer, as he can use as much as 200 per cent. in the bath.

Madder. Madder is the root of the *Rubia tinctorum*, a plant indigenous in Asia, but long cultivated in Europe. Formerly it was looked upon as the most important colouring matter for the calico printer. In dyeing, it was used to produce the brilliant Turkey-red on cotton, by a long, difficult, and even dangerous process. In this use it is now supplanted by artificial alizarine.

Madder still finds a limited use in wool dyeing, generally together with other natural colouring matters to produce very fast drabs, especially on thick felted material such as hat bodies, on account of its penetrative power, which is not possessed by its substitutes. Madder gives a wide range of shades with the various metallic mordants.

Both the colouring principles of madder, alizarin and purpurin, are produced synthetically at a much lower cost than an equivalent quantity of natural madder, and the ease of application is altogether in their favour. Madder, however, contains also a brown colouring matter that is absorbed by wool.

Its great penetration makes it serviceable for dyeing thick felts—hat bodies, for instance. Even for this limited use, madder is less and less employed, as certain artificial colours have been invented which give perfectly satisfactory results. These, moreover, can be combined with fustic or logwood in a similar manner to madder.

The Redwoods. These are divided into two categories—the *close* or *hard* woods, such as camwood, barwood, and sandal, also called sanders or saunders wood, and the woods in which the colour is much more soluble, obtained from several species of *Cæsalpinia*. These have a strong family likeness, and are termed indiscriminately Brazil wood or peachwood in the dyehouse. Peachwood has nothing to do with the peach-tree; it is so called because it was imported from Campeachy.

Insoluble Redwoods. The two categories are known as insoluble and soluble redwoods, although the first term is not correct; the hard woods are soluble slowly, and with difficulty.

Mahogany is closely allied to these woods, and used to be employed for very fast drabs on cotton, especially in places where mahogany sawdust could be procured cheaply. The writer has seen a pattern prepared for the instruction of students, but the colouring matter is too weak for practical use.

Camwood is the strongest and most serviceable, and the shades it gives are very permanent.

Barwood resembles camwood, but it is practically insoluble in cold water, and boiling water parts with much of the colour it takes up when allowed to cool. The method of dyeing on wool is to *stuff*—that is, to boil in contact with the wood in a state of sawdust; the particles of wood must mix with the fibre—and to after-treat or *sadden* with the mordant. This is the usual process with the other insoluble redwoods.

Sandalwood is very similar to barwood in its properties, but the solution smells like orris, whereas the barwood concoction is odourless. These woods cannot be used on silk, the method of dyeing proscribing it. Barwood red on cotton was known as *mock Turkey-red*, but the alizarines have driven this out of the field. These woods are chiefly used now for compound shades on wool obtained by using them with logwood and fustic.

The Soluble Redwoods. Brazil is said to have obtained its name from its flame-coloured

forests (*brassas*, a glowing fire), but the "Brazil woods" now come from many parts of the world.

Brazil wood was a Government monopoly at one time, and was hence called by the Portuguese *queen wood*. The Brazilian supply near the coast was used up, and although it was grown in abundance in the West Indies the demand for it was so great that the supply was quickly and extravagantly exhausted. There is probably very little Brazil wood properly so-called on the market.

Pernambuco, Lima wood, Sapan wood, Peach wood, which is also called *Nicaragua wood*, or *Santa Martha wood*, and *Jamaica wood*, all contain the same colouring matter, *brazalin*, in varying qualities. They are used to some extent in silk dyeing, giving shades, however, inferior to those obtained from cochineal. They are principally used on alum-mordanted wool to get bright crimsons, and to dye purples on a chrome mordant.

Fustic. This is the wood of the *Morus tinctoria*, grown principally in Brazil and the West Indies. It is known also as old fustic, Cuba wood, and yellow Brazil wood. Fustic is not used in cotton dyeing, and only on silk for compound shades with other dyestuffs. It is principally used as an extract procurable in red or yellow shades, and for heavy woollens. It is the most important of the natural yellow dyes, and has been greatly in request lately as the constituent for khaki. On a chrome mordant it gives the pretty shade known as *old gold*. The brightest and fastest yellows are got with stannous chloride as a mordant. It is used principally, however, for compound shades, as the yellows are not very permanent. With copper sulphate it gives olive shades, and the dyeing can be done in a single bath. Dark olives are got with ferrous sulphate as a mordant, and the single-bath method gives good results.

Fustet or *Young Fustic.* This is the wood of a species of sumach, *Rhus cotinus*, and was formerly called *Venetian sumach* by English dyers. The French dyers first called it *fustet* or *fustoc* and as the names *fustet* and *fustic* were easily confounded, "young" was added as a qualification, although fustet has no relation to old fustic. It was never, we believe, used for cotton, and the yellows and oranges it gives on wool are very fugitive. Hummel, in 1885, said that "it would be no great loss if it disappeared from the market altogether," and it is now almost obsolete.

Bark or *Quercitron.* This is the inner bark of an oak, *Quercus nigra*, indigenous in North America. The decoction has a yellow-orange colour, and much is used fresh. It is sold also in the form of an extract. It contains a large percentage of tannin, and was formerly used for dyeing cotton yellow. It is now principally used in calico printing.

Flavine. This is a preparation of quercitron bark imported from America as a fine, light dun-coloured powder. It is stronger and gives brighter shades than bark, and has almost superseded quercitron in the dyehouse. Its principal use is on wool, to give bright orange shades on a tin mordant.

Annatto. This dyestuff, sometimes written *annotta* or *arnotto*, is obtained from the pulp enclosing the seeds of the *Bixa orellana*. Its importance in England largely depends upon the necessity of imparting to butter the "natural" colour which the British public expect to find. It is still used in silk dyeing, however, for orange shades in a soap-bath, no mordant being required, and for the compound shades with indigo, logwood, and other natural dyestuffs.

Weld or Wold. This plant, *Reseda luteola*, a species of mignonette, is extensively grown in France, and comes on the market as a dyestuff in small, dried bundles of stems. The more slender these are the better the quality. With alum it gives the fastest and purest yellow shades on wool procurable with a natural dyestuff, but it is weak in colouring power, and this greatly limits its use. The green known as "carriage-green" used to be produced by topping indigo-dyed cloth with weld. Weld is the most important natural yellow for silk, as the colours are fairly fast to light and soaping.

Safflower. This is the dyed florets of a species of *Carthamus*. It contains a red dye, and a worthless yellow colouring matter. According to Charles O'Neill, "it yields the most delicate shades that the art of the dyer can produce." It has also the distinction of being the only dye formerly used for legal "red tape." It yields very fugitive shades, however, and is now hardly ever employed. In both silk and cotton dyeing it is almost superseded by safranine, an artificial dyestuff.

Turmeric. This is the rhizomes of various species of *Curcuma*. They resemble ginger, and are put on the market in the state of powder. It is a substantive colour, going on to all fibres direct; in fact, no mordant has been found for it, and it produces very fugitive shades. It finds a limited use, however, in mixture with some of the natural dyestuffs, and with the acid colours on wool. It is occasionally used for oranges and yellows on silk.

Orchil and *Cudbear.* A species of lichen known as *Rocella*, found in great abundance in the Canaries and the Cape de Verde Islands, gives a colouring matter sold as paste under the name of orchil, or archil, or as a red powder called cudbear. A dry paste used to be prepared and sold as *persis*. Several preparations known as *orchil carmine*, *fast orchil*, and *French purple* are made, but are almost obsolete. Cudbear gives a bright bluish-red on silk, and is still used. On wool it is simply applied without mordant in a slightly acid bath, and gives depth and richer tint to reds dyed with safflower and cochineal. The shades are not very permanent, and these lichen colouring matters are largely superseded.

Cochineal. Cochineal is a small female insect, the *coccus cacti*. It was thought to be the grain or berry of a plant, and the tints produced with it are still sometimes called "grain colours." It gives the finest procurable shades of crimson, red, purple, and scarlet on wool and silk, but it has been largely superseded by the azo dyes, and by far the greater portion of cochineal imported into England goes to the confectioner. The colouring matter, carmine or carminic acid, is extracted from it on a large scale in France, and is used for colouring artificial flowers. Its principal use in England was for army cloths. With a mordant of tin salts it gives a scarlet, and with alum a crimson on wool, and these are practically the only uses to which it is now put. The scarlet is toned by the addition of a little yellow dye, usually flavine or fustic. Crimsons and scarlets were formerly dyed on the same mordants on silk, but the shades are not very fast to light, and the azo dyes are almost exclusively used.

Kermes. This is the dried bodies of another species of the coccus insect, and the colouring matter is identical with that of cochineal. It is very much weaker in colouring power, and even before the days of the artificial dyes it was little used in England.

MERCHANDISE TRAFFIC

WHEN the man in the street speaks of a goods train he has in his mind a train conveying either merchandise or minerals, and does not pause to differentiate between what really form two distinct classes of traffic. To a certain extent he is warranted in confusing the two. For the purpose of classification, *goods* are defined as anything entering the Railway Clearing House Classification Schedules A, B, C, and Numbers 1, 2, 3, 4, 5, the basis of which classification is their value or the cheapness with which the articles can be conveyed, while other factors that are taken into consideration may be summed up as weight and bulk, method of packing, and liability to damage. Further, the Clearing House "Rules and Regulations" only speak of a *goods train*, which "is understood to include all trains except those composed of coaching stock." However, in practice, the mineral traffic is a thing apart, and it may be defined as covering the transport of coal, coke, iron ore, and patent fuel, while some companies include in it granite, slag, and limestone—in short, the heavier and cheaper articles. The mineral traffic conveyed annually by the railways of the United Kingdom now amounts to 350,000,000 tons, and this traffic consists largely of coal.

Private Ownership of Waggons. The first railways were constructed, like the canals, with the idea of the motive power and the moving or rolling stock being supplied by the public. The railways were to be improved roads, for the use of which customers—that is, the old-established firms of carriers—were to pay tolls, while either renting or providing their own terminal conveniences.

Presently complaints became general that the carriers stood between the public and the companies, so in 1847 the London and North-Western Railway entered into a new arrangement, by appointing the carriers merely cartage agents for the collection and delivery of goods, and by taking over the sheds and warehouses which the latter had provided. This system became common to railway companies, and endured for a considerable period, although it proved the source of constant disputes, difficulties, and additional expense. The public requires the movement of its merchandise to be one transaction, from the door at which it goes to its destination. It does not want a middleman in the shape of a cartage contractor. Cartage at a cost price leaves the railway rate to be discussed on its merit; whereas cartage by a contractor, who requires a good profit, exhausts the elasticity of the railway rate.

The modern system of the railway companies undertaking cartage and delivery was gradually evolved as lines extending into districts where no large carriers existed, and, again, as competitive lines sprang up, and the last-comer found that its rivals had already appropriated the existing cartage connections. In these circumstances the railways had to organise their own equipment for collection and delivery. Having once established cartage machinery, the feasibility of getting rid of the carrier-middlemen presented itself to the companies. It was some years before the London railways carried any goods other than merchandise and live-stock. When railways generally first accepted the carriage of coal, coke, lime, salt, and so on, they decided not to let out their waggons for these classes, which are largely dealt with in private sidings, but to convey them in "private owners' waggons" at a reduced rate. The North-Eastern Railway, however, was bound by statute to provide trucks for mineral traffic, and permitted to make a fair charge for their use. Recent legislation has recognised the general practice of the companies not to supply waggons for mineral traffic, and has expressly enacted that they shall not be required to provide waggons for this traffic.

Spiller's Case. An important case touching the right of traders to run their own waggons over a railway, and to receive a rebate from the railway rates for their use, was decided by the Court of Appeal in 1910. A firm of Cardiff millers (Messrs. Spiller) expressed a strong desire that their traffic should be carried in covered vans; and because the Great Western Company could not guarantee this, the firm built a supply of 300 covered vans for themselves, contending that sheeted trucks were not suitable for the purpose. The firm also claimed that when they found the waggon they were entitled to a rebate from the actual rate charged, equal to the maximum charge for waggon hire. The company contested this view, on the ground that it was onerous for the traffic to be sent in the firm's waggons, as it necessitated the vehicle being brought back to Cardiff without charge, whereas when the railway company's truck was used the truck was frequently, after being unloaded, reloaded at the station of destination to some other point. The railway company, therefore, would have been doubly affected by the claim—first, by the rebate allowance claimed in respect of the firm's waggons, and, secondly, by the expense of bringing back the empty waggons, and holding them at the disposal of the firm, which did not possess a single yard of sidings. The Master of the Rolls decided in favour of the Great Western Railway, and five other Lords Justices delivered concurrent judgments. So now we know that no obligation rests upon a company to convey merchandise otherwise than Clause A; that is, minerals, and certain other traffic specially mentioned in the Provisional Order, in "private owners' waggons," and that for such traffic as grain and flour a sheeted truck is a "suitable vehicle," and therefore its provision is a "reasonable facility."

There are now about 650,000 private owners' waggons and 750,000 company-owned waggons on British railways. Formerly private owners' waggons were a source of constant trouble and anxiety, as they were run up as cheap as possible, and allowed to lapse into a ramshackle condition. The Midland Railway obtained Parliamentary powers in 1881 to borrow a million sterling for the purpose of buying up from some 300 different owners the 40,000 mineral trucks which were running on its system, and building others for the conveyance of coal and other traffic. Having done this, however, it did

not sufficiently reduce its charges for waggon hire to induce traders to use the railway vehicles, and the consequence is that almost as many private owners' trucks are now to be found on the Midland system as on any other. At last, the insecurity engendered by the bad condition of privately owned waggons caused the Board of Trade to intervene.

The Board issues from time to time a "standard specification," accompanied by drawings and dimensions, to which private owners must build. It also provides that when the waggons are complete, and before they are permitted to run upon the railway, they must be examined by the company's waggon superintendent; and if he is satisfied that all the requirements of the specification have been duly complied with, he affixes to both sides of each waggon a register plate. The waggon is then free to work over that company's or any other line of railway, the arrangement being a mutual one between all the railway companies in the country. The latest regulations for private owners' waggons bear date April, 1903. They enjoin the abolition of dumb buffers as from 1910, but an addendum provides that on and after January 1st, 1914, no waggons will be allowed which are not fitted with spring buffers of approved type. They impose limitations on the tare, with the object of restricting the dead weight to be hauled; all ironwork and springs must undergo specified, rigorous tests; the use of oil in lieu of grease axle-boxes is obligatory, and the pressure at which wheels must be fixed to the axles is fifty tons per square inch, instead of thirty tons as formerly.

Varieties of Vehicles. All mineral waggons are open trucks, whereas merchandise waggons may be broadly divided into the *open truck* and what is variously termed the *box van, covered waggon,* or *cupboard truck.* There is, in addition, a large assortment of specially fashioned vehicles for special purposes—namely, cattle-trucks, fish-waggons, refrigerator vans, gunpowder-vans, ballast trucks, plate-glass waggons, trucks for the conveyance of timber in long lengths [84], low-bedded trucks [81], nicknamed "crocodiles," for transport of anything abnormally high or heavy, such as boilers and machinery, and special "fender" waggons for straw hats and feathers [84]. The transportation of practically all merchandise and minerals in this country is effected by the means of vehicles—open or closed—carried on two axles and four wheels, and having doors at the side adapted to cart level. The mineral waggons [78] have, as a rule, a slightly larger capacity than those intended for merchandise, but some companies discountenance any difference, as they wish all their waggons to be interchangeable.

The standard British merchandise and mineral waggon is the ten-ton open truck (a truck being described according to its capacity and not by its tare, which is the weight of the vehicle unloaded). The open truck began with one plank at each side, which has been gradually extended, with a view to obtaining larger loads combined with greater safety, to a height of from 3 ft. to 4 ft. Closed waggons are not so popular in this country as elsewhere. There is the difficulty of getting a crane into them, unless provided with a sliding roof, which in turn is liable to admit wet; on the other hand, they obviate the necessity of sheeting. Many companies are, however, considerably increasing their stock of box vans; and the cubical contents of the new vehicles, with which the sliding roof is abandoned, are twice as large as those of the old open type of waggon.

Insulated covered waggons have recently come greatly to the fore, owing to the rapidly increasing traffic in chilled meat, fruit, and flowers from abroad. These vehicles are insulated from variations of temperature. The car body is made double, the space between being filled with a non-conducting material. Apparatus for ventilating, refrigerating, and heating, according to requirements, is also fitted. The London and North-Western Company has built hundreds of insulated waggons [82], principally for the carriage of bananas. The fruit is steam-heated in transit, so as to prevent it from ripening a bad colour.

Waggon Marks. It is customary for railway companies to give their own waggons distinctive marks. For instance, the London and North-Western mark is a white diamond, the Lancashire and Yorkshire a triangle within a circle, the North Staffordshire a Staffordshire knot, and the Great Central a star. The tarpaulin sheets of open waggons are also distinctively marked, as a safeguard against loss or theft. Thus, the Midland is a black sheet with an orange border, while the Great Western sheet is scored with crossed bars and griffin's wings. Lastly, every company has its ropes made up with differently coloured strands, though this distinction is not visible unless one of the standard ferrules affixed to each end be lost.

High-capacity versus Low-capacity Waggons. During the last few years a great controversy has raged relative to the desirability of increasing the capacity of mineral waggons. The average capacity of these vehicles is ten tons, and waggons larger than this are considered high-capacity trucks [80]. The exponents of the high-capacity waggons—a vague term, as it covers anything between fifteen and forty tons—allege, with some truth, that owing to the low-capacity system British railways are hauling considerably more dead weight, capacity for capacity, than is the case in some other countries, notably America. Their line of argument is that the adoption of high-capacity mineral waggons would considerably reduce the foregoing source of expense, and, at the same time, tend towards reducing the length of trains, because, given a uniform wheel-base, there would be fewer waggons. However, several technical difficulties stand in the way of the adoption of larger waggons. In the first place, it must be remembered that all turntables, sidings, coal drops, weigh-bridges, and pit screens at collieries, stations, and wharves are designed for the low-capacity waggon. The wholesale alteration of these appliances and accommodations would be a most costly business, while another obstacle is that in the majority of instances they do not even belong to the railway companies, but to private traders or corporate bodies, which could not be compelled to bear the expenses of the change.

Generally speaking, the traders are not enamoured of the advantages claimed for the high-capacity waggon. They fear damage to their small trucks when working with larger ones, and they scent damage to minerals while loading and being conveyed in the latter. Colliery owners carefully guard against breakage of coal, as freedom from "small" enhances its sale. There can be no doubt that there is much greater risk of breakage in loading fuel into large trucks, and also during its transit in the same. Iron ore, again, is said to be depreciated in value when carried in large trucks, for similar reasons. In the case of companies, like the Midland and North-Eastern, which prefer to own all the waggons

running over their line, and also desire to make them interchangeable, the employment of two different sizes of waggons—for merchandise and mineral traffic respectively—is deprecated.

The higher the capacity of a waggon, the longer it takes to unload, as only one checker can be employed at this end. Now, it does not much matter what length of time the unloading of minerals occupies, but the case is very different where goods are concerned, as such consignments must be dealt with expeditiously. Suppose a forty-ton truck be fully loaded with goods, it would take many hours to unload, whereas a ten-ton waggon can be disposed of within the hour. On the other hand, this loss of time would probably be met to some extent by better working. However, setting aside the question of effecting interchangeability, the crux of the problem rests on the fact that in this country there are very few cases which warrant the running of high-capacity mineral waggons—much less high-capacity merchandise waggons.

British Short-haul Conditions. A British mineral train rarely travels for a greater distance than 200 miles, and the coal consignments as a rule are comparatively small. For example, it is estimated that on the London and North-Western 80 per cent. of the coal is carried in consignments of less than 20 tons; and accordingly there would be no economy in employing 20-ton waggons for the transportation of 80 per cent. of the traffic. Nevertheless, there are some openings for high-capacity waggons. Coal passing in large quantities for locomotive use, and a regular traffic between specific points in coal, ore, or bricks, can be conveyed in 30-ton or 40-ton trucks with advantage. Several companies have built waggons of this description for those special purposes. When a waggon attains a capacity of 30 tons it must be carried on bogies [80]. To sum up, it is unlikely that the agitation in favour of high-capacity waggons will succeed as its exponents wish it to succeed, for the simple reason that the idea is based on economical conditions which do not prevail in the United Kingdom; but the movement has been of great value by demonstrating that trucks of a moderately increased capacity—namely, from 15 tons to 20 tons—are likely to ensure success, if the change can be made gradually. The North-Eastern Company now carry the major portion of their mineral traffic in four-wheeled waggons [78 and 88] having a tare weight of 9 tons 13 cwt., and capable of carrying 23 tons, while many other companies are acquiring a stock of 15-ton to 20-ton mineral waggons. These waggons fulfil a want, and confirm the fact that a paying load up to 20 tons can be carried within reasonable dimensions on two axles and four wheels, and with a tare in a ratio of only $2\frac{1}{2}$ to 1, which are results equal to anything achieved with the larger bogie waggons.

Either-side Brakes and Automatic Couplings. Returning to the technical equipment of mineral and merchandise waggons, two points remain to be noticed. First, there is the question of fitting them with either-side hand brakes (that is, brakes capable of being applied or released from either side). The Railway Employment (Prevention of Accidents) Act of 1900 empowered the Board of Trade to impose this obligation on the railways. The rule has not yet been put into operation, but in October, 1911, the Railway and Canal Commission disposed of all objections to it. Therefore, it only remains for the Board of Trade formally to "make" the rule. Meantime, the Great Western Railway has partially conformed to it, being engaged in gradually fitting its stock with the Dean-Churchward either-side brake, while the North-Western, North-Eastern, and North Staffordshire companies are likewise fitting their waggons with brakes of their own. Supposing the rule were made, a time limit of ten, fifteen, or twenty years would be allowed.

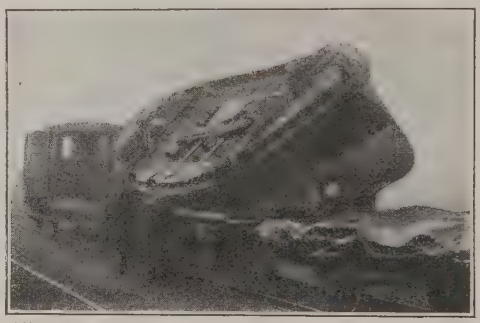
Secondly, there is the question of fitting all waggons with automatic couplers, obligatory adoption of which is also provided for by the Act of 1900. The delay in making this rule is, however, said to be due to the difficulty of finding a suitable form of coupler. Hundreds of automatic couplers have been invented and patented, but so far none appears to solve the problem to the satisfaction of the authorities. This, again, would be a very costly change, in that with automatic couplers it might be necessary to substitute central for side buffers. For the safety of shunters, the use of the coupling-pole has long been obligatory, and great dexterity is displayed in manipulating the present three-link chain couplings with it. A competition known as the "Shunters' Derby" exists, the competitors having to run down a line of waggons, coupling each one, and on the return journey uncoupling them. When the event was held at Burton-on-Trent a few years ago, the winner coupled and uncoupled twenty waggons in 1 min. $16\frac{1}{2}$ sec.

Definition of "C and D" Rates. The cardinal point of difference between the goods and passenger traffic is the very obvious fact that the former does not find its own way to and from the railway, neither does it transfer itself at junctions. In the former case there are two ways of dealing with the articles: either they are collected and delivered by the railway company, when they are charged "C and D" rates—that is, providing for the expense of collection and delivery—or they are brought to and from the terminal stations by the traders, who also undertake all loading and unloading. In the latter case "station-to-station" rates are charged, and all station-to-station consignments are carried in full truck-loads as far as possible. Cartage is provided for in two ways: a railway company either employs its own horses, vans, lorries, and men, or commissions an agent to carry out the whole of this work.

The Cartage of Goods. The staff of the cartage department comprises the following: van boys, van drivers, stablers, van washers, van mechanics, cartage superintendents or inspectors, horse managers, and veterinary surgeons. Van boys are employed only in large towns, where the police regulations do not allow vehicles to be left unattended, and goods run the risk of being stolen from the rear of the vehicle while in transit. In course of time a van boy becomes a single-horse van driver, and is subsequently promoted to the charge of pair-horse, three-horse, and four-horse teams. In certain districts, where very heavy and bulky articles have to be handled, two men are sent out with each van, so as to assist one another in lifting the weights. Some companies call the second man a "book carrier," as he is responsible for receiving moneys and getting the book signed, while his companion, the carman or driver, is in charge of the horses. Companies undertaking their own cartage give the drivers and van boys uniform caps and overcoats, in order to act as an advertisement and protect customers from fraud, while some companies compel their cartage agents to do likewise.

In London and all big towns the major portion of the "C and D" goods—that is, the orders—go through the companies' receiving offices. The staff of a receiving office comprises an agent, clerks, and porters. On the other hand, in the country consignments (as a rule) are collected to order at the consigner's premises and taken straight to the station. The employment of self-propelled vehicles in the cartage department is dealt with later.

The Care of the Horses. The carmen at small stations have to groom and stable their horses, and also to wash their vans. All this is, however, done for them at important goods depots, where the number of horses employed runs into hundreds, and the stables, in consequence, form a separate establishment. In the case of depots situated in the heart of large towns, the absolute necessity of keeping the animals near at hand compels them to be stalled on the upper floors of warehouses, in the arches of bridges, and even in subterranean labyrinths. Here there are a horse-manager, who is entrusted with the health, care, and feeding of the horses (although he does not select what horses are to pull what loads); a veterinary surgeon, with hospital staff; foremen horsekeepers, each of whom has charge of ten horses; stablers; van washers; and van mechanics, for every van is overhauled before making a journey. Moreover, at these depots there is a cartage inspector, who is a salaried official under the station-superintendent or the goods agent. It may be noted that cartage exigencies necessitate the employment of different kinds of horses at different places. Thus, in London, good trotting horses are mainly required, whereas in Liverpool strong draught horses, to pull very heavy loads at walking pace, are essential.



85. A LIFEBOAT POISED ON A RAILWAY WAGGON

Consignment of Goods. Let us now describe the procedure followed when a package or a consignment of merchandise charged at "C and D" rates is handed to a railway company for transit.

The consigner fills in a document known as a *consignment note*, in which he describes the consignment for classification rates, states who pays the cost of carriage—consigner or consignee—and signs the ordinary conditions of the Carriers' Act, printed on the back. There are special consignment notes for special kinds of consignments, such as inflammable liquids, bullion and specie, explosives, and damageable goods. On arriving at the depot, the carman drives over a weighbridge, which registers the weight of his load in bulk.

The reason for taking this weight is to furnish returns of the tonnage entering and leaving the yard, to prevent pilfering, and for the purposes of the bonus system, by which the wages of the carmen are regulated.

The Work of the Goods Staff. The articles next pass into the hands of the working goods staff, which includes the following:

INDOOR WORKING: Porters and checkers, loaders or stowers, callers-off and searchers, shed foremen, inspectors. OUTDOOR WORKING: Capstanmen, shunters, truck-markers, number-takers, yard foremen. The carman gives his consignment notes to a checker. The latter checks the address of each consignment as it is communicated to him by a caller-off during the unloading process, notes whether or not the package or article is in good condition, weighs it, enters its weight on the consignment note, and transfers it, together with the consignment note, to a porter, with instructions as to its destination and the waggon into which it is to be loaded. A goods porter wheels the consignment to the appointed section of the shed, or to where the proper waggon is standing, and here it is taken over by the loader.

The Science of Loading. There is considerable art in stowing or loading waggons. The consignments must be stowed in the sequence in which they are to be unloaded, and they must be distributed evenly over the floor, so as to ensure an even weight on the bearings, otherwise the axles might run hot. An experienced loader will stow three tons where an untrained man would find difficulty in storing 30 cwt. Further, in the case of open trucks, the goods must be packed so that when the truck is sheeted the whole erection will be ark-like in shape, thus allowing rain-water to run off. The loaders are responsible, first, for the safety, and, secondly, for the size of the loads.

Invoice System. Meantime, another checker has added the number of the waggon to the consignment note, after which it is sent up to the invoicing or "shipping" office. An invoice is then prepared, showing the forwarding and receiving stations; the number of the waggon in which the consignment is loaded; the point to which it is loaded; the route by which it is to be conveyed; the names of the consigner and consignee; the number and description of the packages, together with any marks (for some merchandise is conveyed under specific marks); the weight, showing whether carted, non-carted, or mineral; the rate per ton; the charge, whether it is "paid" or "to pay"; and any charges other than those for actual carriage, such as shippers' fees, agents' fees, etc., technically known as "paid on," if it is to be charged forward. The invoice either accompanies the goods themselves by being handed to the guard of the train that conveys it, or by being affixed to the waggon side, or it is sent by post. At any rate, the invoice is supposed to reach the receiving station—that is, the station to which the consignment is loaded—by the time the goods arrive there.

The System of Loading and Transferring. The shed foreman is really responsible for the proper loading of the waggons with safety, efficiency, and economy. He has to see that two waggons are not used where one would suffice, and that before leaving the shed each waggon is properly sheeted, doors shut, and everything safe for it to proceed on its journey. The shed foreman is the goods agent's deputy and right-hand man, but at the more important depots he has an inspector over him. The system of loading goods is as follows. When there is not a sufficient number of articles forthcoming to make up a full truck-load to one destination, a truck is fully loaded to what is termed a *transfer point*, where the goods

are re-sorted and combined so as to give good loads on to their respective destinations. On coming to a transfer point with another company, the fully loaded trucks containing heavy consignments are passed through, while the smaller consignments break bulk, and perhaps have to be carted some distance. A few of the great junctions—Crewe, for example—have tranship sheds where nothing but the work of transferring goods from train to bench and from bench to train is carried out. In the case of smaller consignments, the weight of which is too light to warrant the running of a special truck-load, the station truck system is employed. These latter trucks do not travel for long distances, and they work regularly on local goods trains which call at every station en route.

"Inwards" Traffic Methods. Having explained how the "outwards" or forwarded "C and D" traffic is dealt with, it will be understood that the procedure with the "inwards," or received, is mainly a reversal of the foregoing, with one or two refinements added. For example, immediately on the arrival of a main line train at a big depot, it is met by a "truck marker," who, from particulars supplied by the delivery office, chalks for their proper discharging berths those waggons containing "order goods" (to await orders) or full loads. Again, waggons containing goods for districts that can be more advantageously dealt with by another station, or for which forwarding instructions have been received, are also relabelled by the truck marker, thus saving unnecessary shunting and delay.

Many vexatious incidents arise to interfere with the smooth working of the traffic, and the chief of these may be classed under four heads—namely: (1) goods arriving without invoice; (2) discrepancies between the invoice and the goods actually received in the waggons; (3) invoices arriving without the goods; (4) goods accidentally trucked to the wrong position on the shed platform. Special cut-and-dried methods are applied for rectifying each of the above errors, and, in the case of the last named, the services of skilled men, known as "searchers," are requisitioned.

Arrangement of Goods Depots. The special accommodation provided for dealing with the merchandise traffic naturally varies in size and equipment according to the volume and description of the goods to be handled. In ordinary circumstances, this accommodation is situated adjacent to a passenger station, but in large towns there are distinct goods stations or depots, which, as a rule, are located as near as possible to the centres of trade and industry, although they may be some distance away from, but, of course, physically connected with, the main line of the railway company. For example, in London the City depot of the London and North-Western Railway is at Broad Street, which is reached by means of the North London Railway via Camden and Dalston; that of the Great Northern Railway at Farringdon Street; that of the Great Western at Smithfield; and that of the Midland at Whitecross Street—access to all the latter being obtained over the Metropolitan line. The peculiar accommodation set aside for goods comprises sheds, warehouses, cattle-pens, turntables, and sidings.

The arrangement of sheds and warehouses has always been a subject of controversy. No standard principles exist, for every company has evolved its own scheme as best suited to its own peculiar requirements. Broadly speaking, however, the laying out of goods accommodation must be governed by the exigencies of the three different kinds of traffic into which the question resolves itself—namely: (1) local traffic (traffic which begins or ends its journey at the station); (2) transfer traffic (traffic loaded to the station for the purpose of being transhipped into other waggons and forwarded to destination); and (3) warehouse traffic (traffic in goods which are to be stored, awaiting orders for forwarding or delivery). A shed that deals with both receiving and forwarding traffic must clear out of the former early in the day, so as to be able to dispose of the latter at night. The "rush" hours at an important goods depot are from 3 a.m. to 8 a.m., between which hours the "inward" traffic is steadily arriving, and from 6 p.m. to midnight, when the outwards traffic is being despatched. In the case of depots like Camden, where several thousands of tons have to be disposed of every twenty-four hours, one section must be completed before it is possible to tackle the other.

Lay-out of Goods Shed. A typical big goods shed consists of an array of platforms, with lines of way on each side of the ground level, and an upper floor devoted to storage or office purposes, while underneath the shed lines are capacious cellars for the storage of beer, bacon, hides, and such commodities as can be lifted or lowered direct between the cellars and the carts or railway waggons, by means of suitable cranes. It will be understood that the shed lines are used only for the loading and unloading of ordinary goods carried at "C and D" rates, which comprise all fragile or damageable articles, the mineral traffic, together with "C and D" consignments of greater weight or bulk, being dealt with in the open, where more powerful cranes can be installed. A large goods shed is mapped out so as to facilitate the work of the carmen, porters, loaders, and checkers. The walls of the cartage space bear number plates, corresponding to the numbers of the various districts into which the collecting and delivery area is divided; thus each driver knows where to station his dray. The platform pillars are hung with destination boards for the information of the goods porters and loaders, and the right waggons will be found opposite their respective boards. Lastly, to facilitate the handling of the articles, power or hand worked cranes are liberally provided on the loading and unloading platforms for both carts and railway waggons.

"Mileage" and "Running" Sidings. The lines of way in the open are divided into "mileage" sidings and "running" sidings. The former, which are arranged in pairs, with room for a roadway between each pair, are utilised for the loading and unloading of "station-to-station" consignments, together with abnormally heavy "C and D" consignments. The "running" sidings are groups of lines for shunting operations, and not for the reception or delivery of goods. All shunting is performed either by engines, hydraulic or electric capstans, horses, or gravitation, with the staff of shunters, whose grades are superior foreman, foreman shunter, shunter, and assistant shunter.

The Goods Shunter's Arduous Task. The chief yard foreman is responsible for the shunting operations, but he delegates his responsibility to the superior foreman. The latter must be an intelligent man, thoroughly conversant with the geography of the railway. His art lies in accomplishing the greatest possible amount of work in the

minimum number of movements. Shunting is arduous and dangerous work. The men are out in all weathers, and are exposed to serious risks of being run over, as not only do the trucks move up and down the parallel lines of way in a constant stream, but in many yards they are transferred from one track to another by means of turntables and lines running at right angles across the yard. Formerly, shunters were exposed to further risks by having to get between vehicles for the purpose of coupling or uncoupling them, but the obligatory provision and use of shunting-poles has obviated this. The object of shunting is, of course, to classify the outwards waggons in complete trains, to marshal them in district and station order in their trains, and to split up the inwards trains by picking out the waggons to be unloaded. The latter have then to be shunted into the goods shed or into the "mileage" sidings, where they must be properly placed for the trader to reach easily with his carts.

86. SHUNTING WITH HYDRAULIC CAPSTAN

"Dressing the Yard." In order to facilitate and economise the work of "dressing the yard," which at important centres is an operation of immense magnitude, difficulty, and costliness, schemes of marshalling sidings of elaborate construction and of great extent have been laid down.

There are three ways of laying out large shunting yards—namely, for flat, gravitation, and hump shunting respectively. Under the system of flat shunting the sidings can be laid in parallel lines, with rows of turntables across them, worked by hydraulic [86] or electric capstans. This arrangement cannot, however, be applied to the other two systems. An arrangement which lends itself to either system, and is the one most commonly in use, is to have sets of sidings in the shape of a fan or gridiron, with a neck or siding, which represents the handle, at one or both ends.

Gravitation Shunting. Gravitation shunting, of course, means that the sidings are laid with a falling gradient, utilised so as to economise power. This principle is applied in the modest siding accommodation of the wayside station, where it was practised at a very early date. Presently it was elaborated for dealing with special classes of traffic, such as loaded or empty mineral waggons, and successfully adopted in the first instance by the North-Eastern Railway for coaling ships at Jarrow-on-Tyne and for "sorting" mineral trains at Shildon. At other places, such as Darlington and the Chaddesden sidings near Derby, with the assistance of locomotives or horses, advantage has been taken of a slight gradient to accelerate the shunting, but at no place had an inclined plane been specially constructed to sort *and marshal* mixed goods traffic by gravitation alone until Mr. H. Footner, of the London and North-Western Railway projected the famous Edge Hill "gridiron" siding, on the outskirts of Liverpool. The scheme began to take shape in 1873, but nineteen years elapsed before it was brought to perfection, at an outlay of two millions.

87. CHAIN DRAG AND HOOK FOR ARRESTING RUNAWAY WAGGONS

Edge Hill "Gridiron" Sidings. The sidings are situated at the east end of the Edge Hill passenger station, north of the main lines to Manchester, the North of England, and Scotland, and have direct connections with the various goods depots in Liverpool. The main lines are crossed by over-bridges, so that trains to and from the depots are enabled to arrive and depart independently of the passenger trains which run through Edge Hill passenger station to and from Lime Street station, Liverpool. The goods depots, which are in communication with the sidings, are as follow: Alexandra and Canada Docks depots via the Bootle Branch on the north; Waterloo and Wapping goods depots by tunnels under the city to the docks, to the north and south respectively of Edge Hill station, the former also being used for the American special passenger trains to and from the Riverside station of the Mersey Docks and Harbour Board; Edge Hill goods, coal, and agricultural depots—direct; Garston Dock depot on the south.

The sidings consist of (1) the reception lines at the summit of the incline; (2) the sorting sidings, into which the waggons, when separated, first run; (3) the "gridirons," through which the trucks are filtered, so as to make them take their proper order of precedence in the train; (4) the departure lines, which receive the trains in their complete state, and where the engines are attached to take them away. On the arrival of a set of waggons in the reception lines, the rear brakes are applied, the engine is detached, and on each waggon a truck-marker chalks the number of the sorting siding it has to enter. The waggons are then let down the incline, the shunters passing the number on by hand or lamp signal to the men who have charge of the points. This process gives each sorting siding a separate train, although the waggons composing it are in indiscriminate order, but by a repetition of the operation the waggons of each train are separated in the "gridirons," whence they are lowered one by one into the departure lines in their proper sequence. The gradient of such sidings varies according to the requirements. It may begin at from 1 in 40 to 1 in 60, and finish up at from 1 in 100 to 1 in 300. Much depends, however, upon the resistance to be overcome from points, crossings, or curves. All the curves are of the same radius, so that the resistance offered by each may be the same.

Arresting Runaways. The shunters are provided with brake-sticks, which they insert between the wheel and the frame to steady the vehicles in descending, and they also use these

implements for letting down the brake-levers as required. Runaway waggons are arrested by means of a "chain-drag" apparatus [87]. This consists of a heavy iron cable, wound on a drum, which is placed in a receptacle between and below the level of the rails; a steel hook attached to the cable is fixed at the height of the waggon axle, and is worked by a lever, which also works a signal. When the line is clear for a train to pass, the hook is kept lowered; but if it is desired to stop a waggon, the hook is raised and catches the axle of the waggon, and the heavy cable being drawn out of the tank by its weight, when dragged over the ballast, so brings the runaway to a standstill. The Edge Hill yard covers an area of 200 acres, comprises 57 miles of running lines, and deals with 3000 waggons per 24 hours. The Great Northern Railway has a similar yard for the concentration of its mineral traffic at Colwick, near Nottingham.

"Hump" Shunting. "Hump" shunting was introduced into British railway practice by the Great Central Railway. It is of American origin, the idea being that where no existing gradients lend themselves to laying out elaborate marshalling yards, the necessary gradients shall be provided by the construction of artificial hillocks or "humps."

Between the years 1904-6 the Great Central Company laid out a large concentration yard at Wath, in the South Yorkshire district, the sidings being constructed with a "hump" in the middle, whence the waggons gravitate in both directions. Traffic from 45 collieries lying on every side is worked to this centre in any order, to be sorted, marshalled, and despatched in full through-train loads. Returned empties are similarly sorted out for their respective collieries. When a train has been left in the reception sidings, it is propelled to the top of the "hump" by a powerful twelve-wheeled engine, specially designed for the purpose, and from there, beginning on a falling gradient of 1 in 40, the waggons continue down the incline till they reach the level, and thence pass into the departure sidings. At Wath there are about 40 miles of sidings, and the length from one far connection to the other is 1¼ miles. The distance from the entrance of the siding to the top of the "hump" in each direction is about half a mile. As many as 5000 waggons can be dealt with at Wath in 24 hours.

The North-Eastern was the next railway company to adopt the "hump" system of shunting. This was at North Junction, York, in 1907, and other "hump" yards have since been made at Gascoigne Wood, Hull, and Newport, the two latter being mineral yards.

Views on "Hump" Shunting. An instructive debate on the respective merits of "hump" and "flat" shunting recently took place at York, under the auspices of the York (N.E.R.) Railway Lecture and Debating Society, with yard masters, foremen, guards, shunters, and others participating. The discussion revealed that those assembled were practically agreed on the following points:

(1) That "hump" shunting was a necessity if an average of more than sixty waggons per hour had to be dealt with.

(2) That for small yards a "hump" was not required.

(3) That while shunting by the "hump" method was much more expeditious than by the "flat" method, there was a greater likelihood of wrong shunts and damage occurring with the former method than with the latter.

(4) That the remedy for such mishaps was to propel the trucks to the crown of the "hump" at a speed not exceeding 1½ miles per hour, and to provide an adequate number of brakesmen or "chasers."

(5) That the increased cost of staff for a "hump" yard was more than counterbalanced by the saving in engine cost.

Immingham Yard. The largest railway yard in Europe is that laid out at Immingham Dock, Great Central Railway, which was inaugurated by the King in July, 1912. There are at Immingham Dock, in the form of running lines and sidings, some 170 miles of track, but so scientific is the lay-out that no movement is made with either loaded or empty waggons, or arriving or departing engines, that necessitates the same ground being traversed more than once. Immingham Yard is the third largest in the world.

At Immingham gradients favourable to gravitation are largely employed. For example, the high-level serving roads are so arranged. The loaded waggons gravitate thence into the sidings feeding the coal hoists, which sidings are laid on a gradient that falls at 1 in 100 towards the docks, so that the waggons complete the journey unaided. When the waggon is emptied off the waggon lift it is placed on the level of the empty waggon lines by means of an automatic tilt. The empty waggon lines fall at 1 in 75 away from the dock.

"Number-takers." Before a goods train leaves the yard the chief yard foreman is responsible for seeing that the loads of open trucks do not exceed the limits of the load gauge (a load-gauge apparatus, with swinging bar, is the safeguard), and that no timber-truck, boiler-waggon, or other vehicle furnished with ropes or chains is permitted to start without the ropes or chains being made secure and safe. In all important goods yards, and especially at junctions of any two companies, you will see officials examining the waggons and taking notes. These are the "number-takers" employed in jotting down the numbers and descriptions of all the waggons, and it is from their records that returns are made to the Railway Clearing House. Number-takers are employed by both the railway companies and the Clearing House, but some companies have discontinued the practice, or, rather, relegated the task to the guards, who enter the number of every waggon on the train in a special book.

Duties of Goods Guards. Every goods and mineral train is accompanied by a brakesman or guard, and sometimes by both, for the distinction is only one of grade, the former being a junior and the latter a senior guard. Goods guards are recruited from station porters, shunters, and so on.

Although the guard of a goods train has no luggage or parcels to attend to, he is given plenty of occupation. He has to keep a log, or journal, of his train, like the passenger guard; is responsible for the proper connection and equipment of his train, and has to see that waggons labelled for certain places are put off correctly, while at way-side stations he directs shunting operations. Except in case of emergency, the passenger guard has nothing to do with the actual working of his train, whereas the goods guard, in travelling down steep inclines, must assist the engine-driver by applying the rear hand-brake—care being taken not to skid the wheels—and, where necessary, fastening down a sufficient number of hand-brakes on the

waggons. Guards must not take on waggons loaded with goods liable to be set on fire by sparks or cinders, unless the waggons are properly sheeted. Such waggons must be placed as far as possible from the engine. Every goods guard who has used a van with a stove in it must, before leaving duty, take care that the fire in the stove is entirely extinguished, unless the van has to be sent out again immediately, in which case a small fire may be allowed to remain. Goods guards must not leave their trains until they have been delivered over to the yard foreman, relief guard, or "train meeter." As the running of goods trains is subject to some incertitude, due to the fact that this traffic yields precedence to the passenger variety, special measures are devised in order to obviate the necessity of making the guards work unduly long hours. Goods guards depots are situated at strategic centres of the line; and if a guard finds that he cannot get home within twelve working hours, he may wire to the nearest depot en route for a relief guard, and then, as soon as relieved, he may please himself whether he puts in a rest at the depot barracks or continues his homeward journey off duty. For the same purpose there is a staff of train meeters at all the principal terminal yards, the members of which relieve the guards of incoming trains, and finish up their work for them.

Limits of Load and Speed. The loads of merchandise and mineral trains are arranged according to the speed at which they are booked to travel, which, in turn, depends upon the character of the line as regards curves and gradients, and the power of the locomotives. The standard loads vary from 24 to 60 waggons. With the uninitiated, a misconception is prevalent that goods trains are worked anyhow, the only stipulation being that they do not interfere with the running of the passenger trains. As a matter of fact, the working of the goods traffic is as carefully provided for and supervised as that of the passenger, while it is infinitely harder to arrange, for the very reason that it is constantly being called upon to shunt out of the way of the faster traffic.

The "Train Control" System. A new method of operation, called the train control system, whereby the conduct of the goods and mineral traffic is ordered and regulated by telephone, was recently inaugurated, and seems likely to become general. Wherever adopted, it has effected a remarkable economic revolution in increasing the receipts from the above traffics per train-mile. The aims and objects of the system are to move the traffic from point to point as expeditiously as possible at the times required by the forwarding and receiving points; to obtain the maximum amount of work out of the locomotive power supplied, by using the fewest engines possible, by incurring the minimum of unproductive mileage, by securing the biggest workable loads, and by preventing congestion and standing time by regulating converging streams of traffic; to regulate the working of the trains so as to ensure the trainman getting a full day's work without relief or excessive hours, and to make arrangements for the prompt clearance of traffic from colliery and other sidings, and to assist the rolling stock department in the distribution and supply of waggons.

The line is divided into districts, with a control office for each district. This office is connected by a special installation of telephone circuits with every signal-box, station, and goods yard on the division; but these circuits must be inaccessible to any but the operating staff. Under what is known as the "selective" system, a call from the control office does not ring up all the bells on the line (in which case the men have to listen and count the beats until they see whether or not the signal is for them), but enables the controller to communicate direct with whichever station he requires, though there is also an additional contact for giving a general call. Further, the control office is connected with the public telephone service, so that freighters can ring up the controller, and inform him of their needs.

The Controller at Work. The controller sits at a long table, sometimes wearing a head-receiver and chest-transmitter, which allow him to receive and transmit telephone messages while leaving both hands free. In front of him is a cabinet fitted with a number of keys and switches, each of which is associated with one of the signal boxes or stations. And over the table may be suspended a "graphic train-control board"—that is, a map of the area he controls, showing not only the running lines and junctions, but also the loops, and refuge, private exchange, marshalling, storage, and loading sidings.

It will be understood that the equipment of offices varies somewhat with different control systems, but, whatever the arrangements, all aim at enabling the controller to give his orders in a manner conducive to safety and efficiency, and at furnishing him with a visual record of the position of any train at any time. The principal duty of the controller may be described in a few words. It is to "speed up" the working of the traffic within his area, so as to augment the capacity of the track, engine power, and rolling-stock. At frequent intervals the controller is advised, from every point where traffic is dealt with, of the arrival of trains, of their load, and of the amount of shunting, loading, dropping waggons, and so on, they have to perform there. He is also kept informed of the number of waggons on hand, and anticipated requirements. All such information he records on forms called *train slips*. As a rule, there is a booked service of goods and mineral trains, but it is pretty well known that such trains rarely run up to a time-table. A goods train time-table is of little value for the purpose of locating the position of the train at any time, because there are so many unknown factors in the calculation; they must give way to passenger traffic, and the amount of shunting and other work to be done differs from day to day.

The controller adjusts the actual working to passing requirements. He rearranges the work to be performed by any train, or even alters its destination. He intercepts any booked train which can be dispensed with. He orders a special to be prepared if needed. He can gauge exactly how long a train should be delayed in sidings or in loops and at signals, and if the right time be exceeded he rings up to inquire what is causing the undue delay. In short, the line may be compared to the keyboard of a piano, on which the train controller plays the tune, but it is never the same tune for any length of time.

Economies of the Control System. Everybody concerned profits by the new method of operation. The railway companies employ their engine power and rolling-stock to the greatest possible advantage, and are in a position to remove any idle time spent in sidings, and any tendency to slothful working in the yards; the freighters can rely upon not being disappointed, and greater flexibility of service, and the employees escape

excessive hours of duty, for which the knowledge at his disposal the controller can arrange for relief trainmen, and save enginemen and guards much "walking time," or waiting about. This system of working has resulted in greatly improved facilities, in particular for colliery-owners and shippers, the conditions of whose business vary from day to day, and often from hour to hour. Thus, at a moment's notice the colliery-owner can divert his consignments to another dock, or the shipper can escape paying demurrage on waggons by 'phoning the controller of the non-arrival of the vessel for which a train is in readiness. But the train controller is powerless to meddle with the signalling of the traffic, which still strictly conforms to the Board of Trade requirements. He notifies the signalmen of every alteration of working, but the latter may not suspend the absolute block system in order to speed up matters. On the other hand, the controller may at his discretion suspend certain local or Clearing House rules, relating to trainloads, brake power, and the like, but for this he accepts all responsibility. It is desirable, however, that a careful record should be kept of any control order sanctioning a breach of such rules, so that in case of accident the employee who carries it out may not be involved in any difficulty.

The faster-timed merchandise trains are composed entirely of new, large-capacity cupboard waggons, equipped with oil-boxes and an automatic continuous brake, while the most powerful express engines are employed to haul them.

Goods Rates. The charges upon a railway may be classified as rates, fares, and tolls. A rate is the cost per ton of hauling merchandise and minerals from one point to another; a fare is the cost per mile of carrying passengers in the company's own carriages from station to station; and a toll denotes "a tax or custom paid for passage," as when one company exercises running powers over the lines of another. Tolls may take, therefore, the shape of a fixed allowance per passenger, parcel, or ton of goods, or the amount may be determined by a mileage proportion of the receipts. In addition, companies are sanctioned to charge bonus mileage rates and fares for the use of special works, such as the Severn Tunnel, or Runcorn, Tay, and Forth Bridges, the construction of which entailed expenditure out of the ordinary. For instance, the Severn Tunnel is 4¼ miles long, but the Great Western Company are authorised to charge for the use of it as though it were twelve miles in length.

88. HIGH-CAPACITY MINERAL TRAIN ON THE NORTH-EASTERN RAILWAY, EQUIPPED WITH WESTINGHOUSE QUICK-ACTING CONTINUOUS BRAKE

The Midland was the first railway company to inaugurate a system of train control, and began in January, 1908. The Great Western had installed it on the Monmouthshire section, a district thickly studded with coal-pits and iron and steel works, and serving many great docks. The London and North-Western and Lancashire and Yorkshire adopted it in 1912. These two companies employ large graphic train-control boards in the control offices. The North-Eastern, North British, and Rhymney are other converts to it, the latter company having adopted a "selective" system. In every instance colliery-owners, shippers, and manufacturers are enthusiastic about this method of operation, and are co-operating with the railway companies in the matter.

Express Goods Trains. In this country the merchandise, as distinct from the mineral traffic, has ever been worked at comparatively high rates of speed, and the tendency now is to increase the speed of such trains until they fall little below that of express passenger trains. The Great Northern Railway was the pioneer of "express" goods trains, and at the time of writing boasts of giving a score of these daily, which are timed at inclusive speeds of from forty to forty-five miles per hour. A rate of speed exceeding fifty miles per hour is, however, often maintained from start to stop by trains conveying fish and other perishable consignments.

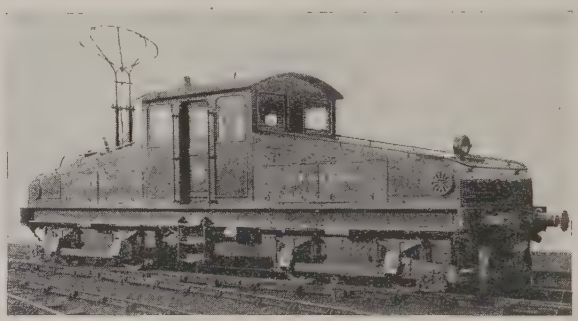
The rates, fares, and tolls to be charged upon a railway are, in a sense, regulated by Act of Parliament, and the maximum charges now authorised to British railways for the conveyance of merchandise and mineral traffic date from 1892, when, for the purpose of fixing charges, all goods liable to railway conveyance were classified under eight different heads, three of which are known as classes A, B, and C, and the remainder as classes 1 to 5. The system of classification followed still is, as it always has been, according to the weight, bulk, value, method of packing, and liability to damage of the articles. Class A traffic includes coal, coke, iron ore, and patent fuel—in short, the heavier and cheaper articles which are carried at the lowest rates, while at the other end of the scale is Class 5 traffic, which covers furniture, china, straw hats, and perfumery—in short, the more valuable or fragile articles, for which rates are naturally highest.

Important Rules. Classes A and B are applicable to consignments of four tons and upwards. In Class A the ordinary rate stipulates that the freighter shall supply trucks. If the railway company supplies trucks, an additional charge is made. In Class B the normal rate applies to traffic in railway companies' waggons, and if the freighter supplies the waggons an allowance may be made. In neither A nor B do the rates cover any labourage. Class C is applicable to consignments of

two tons and upwards, and the ordinary rate covers loading and unloading by the companies, but not cartage. Classes 1 to 5 apply to consignments of from 3 cwt. to 2 tons, and, unless otherwise provided, the rates include collection and delivery within the boundaries prescribed by the companies at the various places. Consignments not exceeding 3 cwt.—technically know as "smalls"—are charged in accordance with the regulations and scales for small parcels by merchandise trains.

The Goods Clerk's Classic. The statutory classification of goods not being considered sufficiently comprehensive, the Railway Clearing House issues a "General Railway Classification of Goods by Merchandise Trains," which has been appropriately christened the "Goods Clerk's Classic." This latter volume is published annually, and a specimen page is reproduced below.

A part of the book is printed on yellow paper, which portion contains a special classification of explosives and other dangerous goods, while there is also a private supplement on pink paper which contains instructions for the information of railway servants alone respecting the method of charging for articles of unusual length, weight, or bulk, articles requiring an exceptional truck or a special train, articles not packed or insecurely packed, any wild beast, and specie, bullion, plate, and statuary, for which the railway companies are authorised to charge "any reasonable sum they think fit." In the present statutory classification, Parliament, instead of providing for all unenumerated articles in the highest class, has placed them in Class 3, but an appeal is permissible on either side. Thus, if a freighter deems that a traffic in which he is interested be too highly placed in Class 3, he may apply to the Board of Trade to have it reduced, while, on the other hand, if the railway companies consider that its classification in Class 3 be too low, they may apply for it to be transferred into a higher class. A case in point was the successful application on the part of the companies to have gramophone records placed in Class 5.



89. ELECTRIC LOCOMOTIVE FOR GOODS TRAFFIC ON THE N.E.R.

Legal Restrictions Against Increasing Rates. Another "Railway and Canal Traffic Act," passed in 1894, renders it obligatory for the companies to prove to the satisfaction of the Railway Commissioners, if challenged, that any increase of rate made directly or indirectly since December 31st, 1892, is a reasonable increase; and for this purpose it is not sufficient to prove that the rate is within any limit fixed by Act of Parliament. The provisions of this latter Act have had the not unnatural effect of making the companies timorous of temporarily lowering during bad times what is a fair rate from fear of incurring litigation should it be subsequently restored to its original height when the depression has passed away.

In 1913 was passed a Railways Bill to carry out the pledge given to the companies by the Government at the time of the strike in August, 1911. This measure only contained one important clause, namely:

"Where on a complaint with respect to any increase (within the maximum) of any rate or charge under Section 1 of the Railway and Canal Traffic Act, 1894, the railway company proves to the satisfaction of the Railway and Canal Commissioners—

"(*a*) That there has been a rise in the cost of working the railway, resulting from improvements made by the company since the 19th of August, 1911, in the conditions of the employment of their staff (except that they may not plead increased wages to the passenger train staff); and (*b*) that the whole of the particular increase of rate or charge of which complaint is made is part of an increase made for the purpose of meeting the said rise in the cost of working; and (*c*) that the increase of rates or charges made for the purpose of meeting the rise in the cost of working is not, in the whole, greater than is reasonably required for the purpose; and (*d*) that the proportion of the increase of rates or charges allocated to the particular traffic with respect to which the complaint is made is not unreasonable, the Commissioners shall treat the increase of rate or charge as justified."

Ireland is excluded from the Bill, as the Irish railways have not accepted the conciliation scheme of 1911.

GENERAL RAILWAY CLASSIFICATION OF GOODS, 1905. 71

Iron and Steel—*continued*	Class.
Wheel Centres, *Locomotive* ..	C
In less lots than 2 tons ..	1
Wire (*iron*), not packed or wrappered	C
Wire, *iron*—Staples (of iron wire) sent with Iron Wire to be charged at the same rates as the Wire.	
Wire, *steel*—Staples (of steel wire) sent with Steel Wire to be charged at the same rates as the Wire.	1
Wire (*steel*), *not packed or wrappered*	C

Adjustment of Rates. In practice, the railway companies rarely avail themselves of their maximum charges. The principle of the companies is to charge what the traffic will bear —that is, rates based not on the cost of the service to the railway company, but on what it is considered the freighter can and ought to pay for it. Within their statutory maxima the companies are free to adjust their rates on a free commercial basis, subject to the foregoing provision regarding increase of rate. Thus, they may charge differential rates, in contradistinction to uniform mileage rates, but one thing they are debarred from doing is to establish a bounty system, or to give one trader undue preference over another.

As to what constitutes undue preference is, however, a very thorny question. For example, different rates charged for consignments of coal, grain, and agricultural produce carried between the same points, one for export or import and the other for home consumption, are not deemed to exhibit undue preference, as in the former case what is invariably the lower rate is considered to be justified by the much larger volume and greater regularity of consignments carried to and from the ports than between inland stations.

Machinery of the Rates Office. The head "rates office," which is entrusted with the making and keeping accounts of rates and the like, forms the busiest and most complex branch of the goods managerial department. Each district goods manager also has a "rates office," whose proceedings are regulated by the headquarters office, but which in some cases is empowered to fix local rates within the district without first referring them to headquarters. A rate-book must be kept at each station, where any trader may inspect it on demand.

The head and other important "rate offices" are subdivided into three departments—one to deal with merchandise rates, another with mineral rates, and another with live-stock rates.

Millions of rates, of course, are already in existence, while how they came to be so is best explained by recapitulating the procedure followed when a company receives an application from a trader to quote a rate between any two points not scheduled in the rate-book, and perhaps for some newly invented article which is not found in the classification book. In the latter case, the first thing to be done is to decide how the article in question should be classified.

In calculating a rate, various interests are taken into consideration—the value, nature, size, and quantity of the consignment (the quantity, whether a few tons or several trainloads, being a most important factor), cost of service, consumers' interest, producers' or manufacturers' interest, possible competition by rail or water, possible competition from other produce districts, geographical disadvantages to be overcome, and margin of profit.

Fixing Through and Competitive Rates. Through and competitive rates—that is, those rates in which more than two railways are interested—are to a large extent governed by conferences. There is the English and Scotch Conference, which explains itself; the Normanton Conference, which controls almost the whole of the competitive rates in the North not dealt with by the former; the English-Irish Conference; the Birmingham and South Staffordshire Conference; the Metropolitan Conference, and a host of minor local conferences, such as the Mersey ports.

Where only two companies are affected in the fixing of a through or competitive rate, the rates clerks meet to discuss the matter, and both companies are bound to publish the agreed rate upon the same day. The analysis of a "rate" reveals that the maximum charge which may be made is set out under two heads—namely (1) station and service terminals; (2) rate for conveyance. A station terminal is the maximum charge for the provision of buildings (including warehousing during free period) and sidings, exclusive of coal-drops; and a service terminal is the maximum charge for such labourage as loading, unloading, sheeting, and unsheeting merchandise.

The rate for conveyance is the actual cost of haulage, and this is based upon no hard-and-fast rules, although the axiom is, "The shorter the mileage, the higher the rate." At the chief rates office of a great railway company a complete record is kept of every calculated rate between any two points, and the number of rates runs into many millions. At Paddington the rates library comprises upwards of 1000 volumes.

It is a simple enough matter to ascertain from these volumes particulars about non-competitive or local rates between any two points, but none but an expert rates clerk can trace those of through and competitive rates, which are common to several companies. At headquarters a special "noting staff" of clerks is kept constantly employed entering up all new rates as they are issued, together with keyed references to the authority under which each rate was promulgated.

A separate department exists for calculating and keeping account of the passenger-train rates for parcels, and similar packages. These rates are fixed by the superintendent of the line, or, in the case of the North-Eastern and Great Northern Railways, by the chief passenger agent.

How Disputes are Settled. There is a specially organised statutory department to deal legally with the various phases of controversy between railway companies, or questions of difference between a railway company and a canal company. This is the Railway and Canal Commission, which, in addition to the above, is empowered to adjudicate upon the question of through rates over different lines where such rates would be of public benefit; to hear and determine cases instituted by the consigner or consignee of merchandise against railways in respect of excessive or preferential rates and charges, insufficient accommodation and facilities, and as to any allowance or rebate to be made from the rates charged, on the ground that the railway company did not perform terminal services; to order traffic facilities, notwithstanding existing agreements; and to apportion the expenses of erecting any improvement, such as a necessary bridge, subway, etc., between a railway company on one side and the applicants for the desired improvement on the other.

By the Act of 1888, under the powers of which the present Commission now sits, the department consists of two appointed and three ex-officio Commissioners. The Board of Trade appoints two Commissioners, one of whom must have had considerable railway experience, while the ex-officio commissioners have to be Judges of Superior Courts in England, Scotland, and Ireland. There are also a registrar and clerk to the Commission.

Drawbacks to Motor Transport of Goods. The question of the employment of mechanical road traction for the collection and

delivery of goods consignments by railway companies, as an alternative to horse-cartage, in restricted areas, is of great importance. Nevertheless, automobilism has not as yet materially affected railways where the cartage department is concerned; that is to say, it has not displaced horses to any appreciable extent in the collection and delivery of consignments carried under "C and D" rates. The chief reason for this is that, in order to render the use of self-propelled vehicles profitable, at least three factors must be present—namely, a fairly long haul, a full load of consignments for conveyance to or from a fixed point, and a clear road. Generally speaking, each of these factors is absent. Whether in country or town, the bulk of the business done consists of the cartage of goods and parcels over short distances, and through congested roads or streets, while the loads themselves are made up of miscellaneous consignments, which are collected or delivered at frequent intervals, thus entailing a great deal of waiting about. In congested thoroughfares a motor vehicle possesses little advantage in point of speed over a horse-drawn; and it is obvious that to keep expensive machinery idle, and consuming fuel and water, during a constant series of intermittent halts, must be a wasteful procedure.

Another drawback is that the same amount of work cannot be got out of self-propelled waggons as from carts and horses. A team of horses can be employed on two or three consecutive trips. There are, say, 400 vans at a goods depot: half the number can be loaded and sent out, and while they are away the remainder can be loaded up. Then, when the former return, loaded with "outwards" goods or empty, it is only a question of transferring the teams to the latter; whereas with motor vehicles the motive machinery would have to be kept idle during both the loading and unloading processes. Again, motor vehicles are not so adaptable for drawing up into what chances to be the most convenient position for loading and unloading, and there are many warehouses in which, owing to the inflammable nature of the contents, their presence is prohibited as a source of danger. Lastly, if the railway companies were to adopt mechanical traction on a large scale, they would be faced by the problems of providing stabling for the vehicles (carts can be left in the open), and of storing the petrol safely.

Advantages of the Motor Lorry. The advantages that may be claimed for the motor vehicle over the horse are: (1) Much of the time travelling to and from the stable would be saved. (2) Feeding time would be saved. (3) Greater radius of action. (4) Speed two and a half times greater. (5) Carries a greater load. (6) Will carry its maximum load up any hill. (7) No need for rest. (8) Can work 24 hours a day if necessary. The conditions under which motor vehicles can be most profitably employed are between self-contained collecting and distributing centres, and between a railway station and a town or village situated several miles apart. In the latter case, a series of passenger and goods motor vehicles has made an efficient substitute for a branch railway.

Different Types of Vehicles. The different types of motor waggons at present in use by railway companies are: steam waggons and lorries for heavy goods transport—that is, for loads of from five tons to eight tons; small steam traction-engines, coming under the Motor Car Act; petrol lorries, for light goods and parcel transport, two-ton, three-ton, and five-ton vehicles. A motor vehicle, with a carrying capacity of two tons, and fitted with steel tyres, and not costing more than £250, is considered the most suitable type for the ordinary needs of railway companies. A heavier type of vehicle, the steam motor lorry, is, however, more useful and economical when there is good loading in every direction.

Steam possesses several advantages over petrol in the heavy goods service—namely, both the initial outlay and cost of maintenance are much less; the deliveries with this class of consignment being chiefly centred at one fixed point, fuel and water are not consumed to no purpose during intermittent calls; the pace being slow, iron tyres can be used; and there exists larger reserve power for emergencies.

All technical matters relating to road motor-cars are delegated to the department of the chief mechanical engineer, while the arrangement of the services and the supervision of the staff rests with the superintendent of the line, who acts in unison with the chief goods manager in arranging the goods-car service.

Organisation and Staffing. The North-Eastern Railway has an officer attached to the chief traffic manager's department who has had a mechanical engineer's training, and he deals with everything connected with the road motors, communicating as follows: with the mechanical engineer upon mechanical matters; with the chief goods manager about goods matters; and with the chief passenger agent about passenger matters.

The Great Western Railway, which was the pioneer of the adoption of mechanical road traction for railway requirements, and which possesses the largest stock of self-propelled vehicles of every description, has organised a special motor-car department, under the ægis of the superintendent of the line, to deal with cars all over the company's system. The headquarters of the department are located at Slough, and there, too, are shops that carry out nearly all repairs. The staff of the department consists of: (1) for indoor working, a chief mechanical superintendent, an assistant mechanical superintendent, a chief clerk, a keeper of retail stores, a tyres and staff clerk, who keeps a register of the mileage of all cars, and a travelling inspector of stores; (2) for outdoor working, a foreman fitter in charge of repair shops, a foreman driver, who arranges the services, a traffic inspector, and a staff of drivers and conductors.

Selection and Training of Drivers. Much of the success of the motor vehicle depends on the drivers, and these should be recruited from the old staff of draymen, who have an intimate knowledge of the town and the conditions of the railway business. To begin with, the companies had to recruit for drivers from outside the railway service, but now they train their own drivers, and the more satisfactory drivers are the men whom they have trained themselves. Drivers are divided into four grades—namely, foremen drivers, leading driver, driver, cleaner-driver. A man is promoted foreman driver from the shops, and every important car centre is placed in charge of a foreman driver.

Candidates for the post of cleaner-driver must be from twenty to twenty-four years of age, although ex-locomotive firemen are accepted at a later age. A cleaner-driver receives a practical training in the elementary mechanism of motor traction, and when passed by the foreman he is allowed to drive one or two trips a day, to relieve an ordinary driver.

The Craft and Trade of Lithography. The Stone and its Metal Substitutes. Lithographic Inks. Colour-printing. Rotary Photogravure.

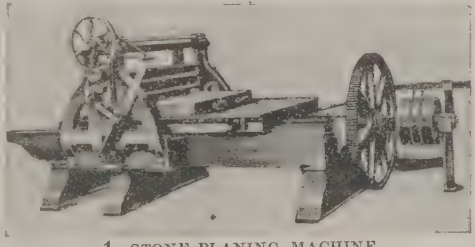
LITHOGRAPHY

LITHOGRAPHY as a business or craft is but young compared with the majority of trades, as its discovery by Alois Senefelder dates back only to 1798. It still appears but a new art to many of the older workers and to those who have intimately investigated its early stages and its early specimens.

As a craft it is one attended with so many difficulties and so many "discoveries" that it is rendered at once pleasant, as well as intricate, to all who may be engaged therein. Not only do these trying circumstances surround the man who has learnt the trade, but they come upon the amateur or novice in the way of surprises which, for some years, are very trying, not to say disheartening. The toils of the trade are not rendered any easier by the traditions which have been handed down through three or four generations of workers who learnt originally only how to work by inspection and under special guidance, without ever attempting to learn why particular methods were adopted. This has proved not only a barrier to progress, but has been the cause of preserving the use of methods and materials which ought to have been discarded at an early date—yet it is these very antiquated notions which are held in such respect by the old-fashioned craftsman.

The Trade of Lithography. From its inception as a business in London about 1818, the trade has been gradually on the increase, and at the present time no fewer than 12,000 craftsmen are directly employed in the production of lithographic prints in Great Britain alone. But although the trade is a small one, it has probably given greater pleasure to a larger number of persons than any other craft, large or small. It has been the means of preserving the works of excellent artists in a beautiful and lasting form, and this has been accomplished at a minimum of cost.

Lithography is responsible for the production of many pictures, as posters and showcards, which have given great pleasure to the whole people, and have assisted in illuminating the dark corners of our streets and otherwise unsightly hoardings. The many ways in which lithography has been brought to bear upon other printing crafts has done much to increase the production and lessen the cost of such arts as engraving and photography. As an illustrative art it has been so often and so successfully called into requisition as to make it practically indispensable to all good publications. Of course, it has had its trials, and it was many years before it ousted such processes as aquatint and mezzotint, as well as much copper and steel plate engraving, from their premier positions.



1. STONE-PLANING MACHINE

In the early days of the art it attracted some of the best artists or sketchers as a means of actually producing their own work directly upon the stone; and one artist, R. J. Lane, became an Associate of the Royal Academy through his superb productions from sketches and original productions directly upon stone.

What Lithography is. Lithography is, as its derivation implies, writing or drawing upon stone. But it has the further meaning of producing copies or prints from a stone. More recently the trade of lithography has been construed to include both printing from zinc (*zincography*) and from aluminium (*aluminography*). If a generic term can be applied, the whole of the different methods should be termed planography, as they are all, virtually, methods of printing from a flat surface or plane. The expression flat surface must be further defined as polished surface, or a grained surface, in contradistinction to a surface etched in high relief. The use of zinc as a printing surface was very little posterior to stone, but aluminium cannot be placed prior to 1890.

All three methods are generally practised by the lithographic printer; and not a few printers are also able to work the various photographic processes akin to, and including, photo-lithography and collotype. So numerous are the methods employed that a lithographic printer has at his command the means of producing any print from the roughest draft plan or specification of the architect to the finest form of imitation photograph, in black or colour. The photographic processes now applicable to lithography are so far advanced that three-colour work is practically within its available bounds.

Lithographic Stones. The stone used in lithography is an exceedingly fine, close-grained chalk or marble, geologically known as a "slate," the latter term having been applied because of the form in which it exists in quarries. These quarries are largely developed around Solenhofen, and extend many miles. But a formation of similar stone runs from Bavaria northwards into Norway and Sweden, and southwards through Switzerland, France, Italy, Spain, across by Corsica and Sardinia, into North Africa.

Formations of the same rock are known in Turkey (around Salonica), Greece, Asia Minor, and the Caucasus mountains, and stones from all these districts have been actually used. A firm in Greece has printed largely from Greek stones; another firm in Berlin has used Caucasian stone; samples from Turkey and Asia Minor have been used in England; and Spanish stone is largely used in Barcelona. French stones have had considerable patronage, but German stones are, without doubt, the finest products, and are used throughout the world: and it is estimated that in a not far distant future the supply will be exhausted. It is this fact, coupled with the cost and weight of stones, which has caused the

introduction of metal plate substitutes, and a strong attempt to compound a stone of similar qualities. The efforts in this direction have been many during the last fifty years; but the want of knowledge of the actual composition of the stone, and the inability to apply the forces which originally compressed this fine chalky mud into a durable rock, have so far been a barrier to its accomplishment.

The statement that failure in making artificial stone may be due to a want of knowledge of the constituents of lithographic slate is perhaps open to criticism. The composition is broadly that of marble, with a little something else which makes the difference—a small difference, but an important one. The original geological formation was probably in progress some hundreds of thousands of years, and the gradual consolidation of the rock was attended by such circumstances in watery surroundings, the juxtaposition of various chemicals and a heavy pressure, that the result is a stone varying in its character just so much—yet very little—from marble that, while the latter is quite useless, the lithographic slate is the only article that can be used. Like marble and chalk, it undoubtedly owes its origin to immeasurable quantities of fine shells—shells pulverised to an imponderable dust—and ultimately deposited in marine waters as a mud, to be converted finally into stone.

The Chemistry of Lithography. The actual processes of lithography, zincography, and aluminography are dependent upon chemical actions. In pursuing these methods, the chemistry of each must always be well known to the printer, for the same chemicals may not be used to attain the same object in each case.

The objects of the chemicals used may be set forth as (1) rendering the surface non-sensitive to grease; (2) rendering the surface sensitive to grease; (3) rendering the work invulnerable to decomposition by acid; (4) rendering the work easily removable by acid; (5) attacking the constituents of the ink used in drawing to make them combine with the printing surface; (6) compounding the original drawing and transferring inks; and (7) compounding the printing inks.

The foregoing brief survey naturally leads directly to a closer description of lithography in detail.

Preparation of the Stone. To obtain an original upon a stone, the stone must be ground down to a slab of equal thickness, so that both surfaces are parallel; then one surface must be ground perfectly level to receive the work. This is accomplished by grinding with sand, by the more remote hand methods, the more recent mechanical appliances [2], or by the latest device of planing the surface in a machine constructed with a long steel planing blade [1]. This machine may be said to be the most perfect appliance yet introduced for the purpose, as it can be gauged to plane off an extremely thin layer of stone, leaving a perfectly level surface all over.

After grinding or planing, the surface is burnished with a close-grained slate, until it presents a distinct, semi-glassy polish, without scratches. Upon this surface, when dry, original work may be drawn or transferred, providing the subject is executed in a line or dot. If the work is of a "grained" character, the polished stone must be suitably grained by sprinkling with fine sifted sand, and rubbing the sand evenly into the stone all over, until the surface is broken up into a fine grain. The sand is then washed off, and the work drawn upon the dry stone with specially prepared ink, called crayons.

The Inks of Lithography. By whatever method the original work is put upon a stone, the ink used must contain certain standard articles, or it is useless. The chemistry of the process starts at the very beginning, and must be kept in view at each succeeding stage. This ink must contain a fat. The fat must be compounded with other fats, solvents, and resistants to make it amenable to the draughtsman's or transferer's art. Generally the ink is compounded of tallow, palm oil, soap, wax, stearin, shellac, bitumen, and a diluent in the form of manufactured printing ink. These are not all used in one ink. Thus, the draughtsman's ink may contain tallow, wax, soap, shellac, and lampblack; the stone transferring ink, tallow, stearin, palm oil, soap, and printing ink; and the copperplate transferrer's ink may be somewhat similar to the last, with bitumen or asphalt in addition. Crayons may contain only tallow, soap, wax, and shellac. Photo-lithographic transfer ink may be similar to plate transferrer's ink without soap. The variety of the lacs is subject to variation to meet the needs of greater or less hardness, or necessity for etching. The object to be attained is to bring into contact with the stone some form of free fatty acid. It is a common knowledge that chalk—lithographic stone—when treated with an acid suffers decomposition, and some compound is the result. This is especially the case when a fatty acid attacks the stone, as the resulting compound is an insoluble salt of the calcium of the stone with the fatty acid of the ink. This compound is the real printing surface produced upon the stone. Similarly, fatty acids (as well as many other acids) attack zinc and aluminium, and in these cases produce an insoluble compound which gives the printing surface.

Etching the Stone. The work having been drawn or transferred upon the stone, the printer proceeds to obtain impressions. If the work consists of heavy masses of thick ink, it must be etched or treated with an acid that will decompose the surplus soap in the ink, and convert it into an insoluble compound with the stone. This is especially necesary with work drawn in crayon upon grained stones. The etch may be a watery solution of nitric acid, or tannic acid, or weak tea, or a mixture of gum arabic solution and nitric acid.

The older method of etching grained stones was with a very dilute solution of nitric acid in water, and it was applied in two ways. The first was to pour over, or deluge the stone with a large jug full of the etch, the whole of it running off the stone into a jug and being used again. The second was to place the stone in a rocking-trough, and fill the trough to the top edge of the stone with the etching solution. In rocking the trough, a wave of etch passed evenly over the stone and left it clear. Both these methods have the pre-eminent advantage of leaving the stone free after immersion, thus allowing the heavy bubbles of gas to escape from the surface before a second etch is begun. In either case, the applications of the etch are numerous before it is completed, and its completion is so much a matter of experience that no rules can be given. This phase of the subject is dealt with apparently in greater detail than it warrants, but it is so important in its bearings that both the principle and methods involved might be applied usefully to some present-day practices.

This treatment having been performed, the actual work on the stone is in a more or less insoluble condition in hot or cold water, and is strengthened by the etch. The work may then be

carefully inked, either by dabbing or rubbing printing ink on it with a soft, fine rag, or by rolling up with ink on a leather roller. In any case, gummy water must be kept on the stone to preserve uniform dampness and to prevent the particles of the original ink from catching upon the surface of the stone and forming a scum upon its surface. Having charged the work with ink, the stone may be washed clean.

Preparing for Printing. If the work be not drawn, or transferred, in heavy, thick masses, the first etching may be dispensed with. Such treatment also applies to work put on the stone in a hard or bituminous ink which has not had time, or does not contain sufficient active agents, to cause its ready combination with the stone, and does not require an etch. After charging with ink and washing clean, the work cannot be considered in quite such a strong condition as necessary, and it should be covered with a fine resisting powder, such as resin, talc, or silica, when it may be lightly etched with dilute nitric acid. The acid actually decomposes any remaining soap in the ink, as well as the actual stone, thereby carrying away many loose particles of grease which have come accidentally on to the surface of the stone. The stone is again washed, and well covered with gum arabic. This gum is of a complex composition, and there is little doubt that it forms a surface on the stone impenetrable to grease. Finally, after the gum has dried, it may be washed off. The work is then "cleaned" or washed out with turpentine prior to final rolling up. It is then thoroughly cleaned up by using a scraper of steel, a wooden stump with acid, or a fine stick of polishing-stone prior to printing the copies from the stone.

Printing Machinery. The printing is usually done in a machine which is fitted with damping-rollers and leather inking-rollers to imitate the the hand-press [8] method of damping a stone well. Printing is seldom taken from the original drawings. Transfers are taken from the originals and put upon new stones, so as to preserve the originals for further use. The originals themselves may be transferred to zinc or aluminium plates and stored away, thus liberating the expensive stones. Wherever possible, the originals should be drawn on the plates. The impression is procured upon paper which is carried on to the surface of the stone upon a cylinder—the cylinder being forced down upon the stone by powerful springs or weights. The action of the machine is to take the stone under damping-rollers, which moisten the surface of the stone to prevent greasy ink catching; thence under a series of inking-rollers. The stone returns under the inking-rollers, getting fed a second time, and in completing its backward journey the printing-paper is brought down upon its surface. The contact of the paper with the stone is reduced to the fine line made by a perfect cylinder coming in contact with the flat surface of the stone, the whole pressure of the powerful weights or springs being brought to bear upon this rapidly moving line of contact [5].

Lithographs in Colour. The feature of lithography which, perhaps, to the general public is the most interesting is the production of coloured prints—*chromo-lithographs*—upon paper, card, earthenware, silk, satin, and other materials. The process is difficult, owing to the great care which is necessary in every detail. An oil painting is reproduced in the following way. A tracing is taken from the picture. This tracing is generally made upon a thin sheet of gelatin, the actual tracing being done by "cutting" in the gelatin with a fine steel point. This copy takes not only the general outline of the subject, but includes the boundaries and contours of all the various colours and mixtures of colours. This *engraving* on the gelatin is then filled in with transfer ink, carefully cleaned, damped (in a special damping book), and laid down upon a perfectly clean stone. It is run through the press and transferred to the stone, to be gummed up and rolled up as ordinary work. It then constitutes the *key* or guide. From it impressions are taken upon a hard-faced paper, or paper mounted on zinc, so that there will be one impression for each colour that the artist intends to use. These impressions are dusted with an offset powder of common red chalk, or aniline, magnesia, and carbolic acid. The latter is the best, because when put upon the stone it penetrates, and the stone may be washed and polished lightly without removing the stain.

These dusted impressions are run down upon separate clean stones, and then constitute the offsets, to which the artist draws all the colours in the proper lithographic ink. When complete, they are all rolled up in the ordinary way, and the impressions in each colour are pulled, one by one, on top of each other until the whole picture is finished. The process requires great care in getting each colour to register, and in the use of colours which, by overlapping one another, give the correct colour-scheme of the original.

Transfer Processes. In the preparation of originals, the stone, zinc, or aluminium is not employed entirely for drawing directly upon. Many originals are executed upon transfer paper. The paper is prepared with a gelatinous surface compounded with an inert dust. Transfers may be taken from copper plates, steel plates, stones, or type, and patched up into the necessary design, when they are transferred to stone.

A branch of the transfer process prepares originals direct from photographic negatives in line, dot, or stipple. It is applicable to producing certain kinds of originals direct upon aluminium, zinc, and even stone. It is applied to producing work by the collotype, photo-stone, and photo-lithographic processes, little used prior to the past twenty years [see pages 5475 and 5478].

Transfers are used in all cases where a large number of prints are produced at the same time.

Metallography. There are but few methods practised in lithography which have been of spontaneous origin, and very few are in existence at the present day (1915) which were not known, although in an elementary way, by the inventor and those who practised the art in its early days, up to 1830.

The use of zinc plates was known to many in France and England before 1840, and the French lithographers asserted that the zincography of England was much better than their own because the zinc plates were manufactured so well in England. Still, zinc was not actually used to any extent until the efforts to introduce coated zinc plates, in 1885, turned the attention of lithographers to the advantages of metal plates.

Metal plates possess very distinct advantages in weight, storage, and portability which gave them a strong recommendation. But the coated plates were not perfect, and machines were not made which would give the best and most economical results. In course of time these deficiencies were overcome, and at the close of the nineteenth century the treatment of zinc had been perfected,

the use of aluminium had been adopted, and several printers' engineers had constructed rotary machines in which either zinc or aluminium plates alone could be used [3 and 10].

In mentioning aluminium, it may be noticed that it was one of the few introductions into lithography which was hitherto unknown until fully described by Bullock and Mullaby, of the United States, in 1891. The wide adoption of these metals did not come about until the perfection of rotary machines, dating from 1895 to 1900, led to the best types of these machines being brought into use from 1899 to 1906.

Although zinc had been in use by a few printers during the greater part of the last century, and various coated zinc plates came in for some patronage from 1885, it may be said that the manipulation of work upon zinc had not received the attention and study which are necessary for its successful treatment. Even at the present time there are many printers who have not used it, and those who have, hold different opinions as to the best methods to be applied.

Zinc Treatment. In describing its treatment the object will be to give methods which are known to be satisfactory and comparatively simple. The main point is to start upon zinc, without attempting to introduce the methods applicable to stone. Thus, most stone-work at the present time is executed upon polished stones, whereas zinc must always be grained. A polished zinc plate would fail to retain an even film of water upon its surface; therefore it is necessary to have it grained. It is not self-absorbent of water, as stone is, and it is not so readily affected by grease. This consideration necessitates that all new work drawn upon zinc plates must be etched first before it can be rolled or rubbed up.

The nature of the etching fluid in use forty-five years ago, or more, was a solution of gall-nuts, with gum arabic and a little phosphoric acid. This etch may still be used with very satisfactory results. But the etch which was adopted for some of the early forms of coated zinc plates has proved very successful upon plain zinc, and is that which is recommended. It is simply equal parts of solutions of gum arabic and a 5 per cent. solution of potassium bichromate. The object of this etch is not a corrosion, as popularly accepted in the term "etching," but is for a purely chemical purpose, and is actually carried out to attack the ink or crayon of the drawing and so liberate the fatty acid, to facilitate its action upon the zinc.

When the etch has been sufficiently applied, the plate may be wiped with a gum-laden sponge to remove the remnants of the etching fluid and any loose ink or crayon. Then it should be gummed over evenly with new and clean gum, using a sponge kept for the purpose. This thin, even film is to be allowed to dry, and upon its dry surface ink may be rolled evenly until the plate is quite black all over.

The next operation is to damp the inked surface, and, with clean bits of rag, to wipe off the gum and ink. When done carefully, the ink on the gum is easily removed, leaving the ink only upon the actual drawing.

The same result may be obtained in another way. If, after the etching and wiping the gum and etch off, the plate be gummed evenly and allowed to dry, the actual drawing may be washed out, or dissolved through the gum film with a solution of turpentine, beeswax, and sensitive bitumen. This solution is now very generally known as a *doctor*. After such treatment the work may be rubbed or rolled up with printing ink.

In either case, when the work has reached the stage of being covered with printing ink, it may then be dusted with talc and etched a second time with gallic acid and gum solution.

From this point the operations resemble those adopted for stone, with such exceptions as must be apparent to the craftsman in using such dissimilar surfaces as zinc, a simple metal, and lithographic stone, a complex earthy mixture.

The extensive use of zinc has created a new line of chemistry in planography, for; while nitric acid is in constant use upon stone, it is never used alone on zinc. The form in which it is used is in a very weak solution with water and alum. This solution, also the outcome of one of the best workers upon zinc before 1890, is now generally known as the *acid-alum solution*. Its characteristics have earned for it a very extensive adoption, not confined merely to zinc, but applicable also to stone and to aluminium.

Concurrently, the use of acids upon metals has caused the much more general use of a simple corrective, in powdered whiting, rubbed on the surface gently with a little water to neutralise the acid.

Take as a pointed example the operation of removing work from a zinc plate, that it may be replaced by a corrected drawing. The plate is well rolled up and dusted with talc, gummed evenly and thinly. Upon the part which is to be removed is dabbed or painted a solution of caustic soda or caustic potash. This penetrates the gum and destroys the greasy drawing on the plate; and to prevent other parts of the work being damaged, the caustic soda is removed quickly, with a sponge well filled with water. The work having been taken out, the area so cleared must be cleaned to take new work. This sensitising or cleaning is effected with sulphuric acid, which, having been carefully applied to the area, is washed off and immediately followed with the whiting treatment. The necessity for this arises through the well-known action of the acids in dissolving or thickening all the work over which such acids have acted. The whiting neutralises the acid action.

The craftsman who has only used lithographic stone will recognise at once how differently zinc has to be treated, and the difference is still more apparent when aluminium is used.

Aluminium Treatment. When original work has been drawn upon aluminium, the first operation in printing from it is to dust it with talc and etch with phosphoric acid and gum. This etch is wiped over carefully and finally wiped off, to be replaced with an even, thin film of gum. When this has dried, the work is washed out, through the dry gum, with a "doctor" solution. After this has evaporated to dryness, it is washed off with gummy water, and the work is rubbed or rolled up with stiff ink, dusted with talc, and etched again with a second application of phosphoric acid and gum.

The great question of retaining a film of moisture upon both zinc and aluminium plates so that it shall be sufficient to prevent ink catching at any parts where it is not wanted, and at the same time not so excessive as to prevent the proper rolling up of the work, has given rise to several methods of treatment, or, rather, to the invention of several solutions having for their object the retention of a hygroscopic film upon the plate. These solutions are known by special names, such as Roderzone, the Tutzschke etch, and as "dopes." Each of

these may be used instead of the second etch, both for zinc and aluminium.

For those who essay to work on either metal, it is a good plan to use these special mixtures until by practice they can overcome the difficulties in other ways.

As a comparison of methods, it may be advisable briefly to describe how work may be removed from aluminium and replaced by new work. The whole of the work must be rolled up in stiff ink and dusted with talc The work is removed by concentrated sulphuric acid, applied carefully with a quill or glass brush. The area is well washed with clean water, and the whiting treatment applied The new work may be drawn or transferred in.

The Choice of Metals. The outline of the treatment of zinc and aluminium here given is in many cases all that is sufficient to the experienced lithographer. It is practically impossible within the limits of this work to enter into every detail of printing from metals—such a description is only possible in a book devoted wholly to the one subject. There are, however, still points of interest and importance appertaining to the subject which can be added.

To those who have never used zinc or aluminium, the question may naturally occur as to which is the better metal for general use. The expert upon aluminium may contend that it is the better metal, and for some few purposes that contention may doubtless be true. For general use, however, zinc possesses all the qualities requisite for good printing.

Aluminium is much lighter in weight and colour than zinc; it is not so brittle, but expands more by heat than zinc. The grain obtained upon its surface is sharper, and is more suitable for very fine direct photographic work than that of zinc. But in the main its general treatment is much more removed from the treatment of stone than is zinc. The use of zinc is better understood, and in the hands of a careful craftsman will yield results equal to aluminium.

Advantages of Metal over Stone. Both metals are more limited in treatment than stone, but the fact that metal plates can be clamped round cylinders and printed from at a greatly increased speed has given them an inestimable advantage over stone.

Although the flat-bed lithographic printing machine has been constructed to run at 1000 or even 1200 impressions per hour for the last 25 years, it has only been in a few cases, and possibly only upon special work, that such a speed has been maintained for nine months out of the year. The rotary machines of 1898–1900 were constructed for 1500 to 1800 impressions per hour, and the minimum speed of 1000 has been easily maintained. The economy in the cost of metal plates compared with stone, the readiness of handling plates, and the speed obtainable by rotary machines have been potent factors in the adoption of metal plates.

To some extent, the use of metal plates has revived the execution of work in crayon, because the plates are grained, and in most ways are suitable for that class of work. It has been through the agency of plates and rotary machines that vast numbers of posters have been produced at comparatively low cost, but it has not been in all cases that poster-printers have forsaken the use of stones. They are still largely used, owing to the special features of stone, which lend themselves so much better to the manipulation of the artist.

A Plate-graining Machine. The second advent of printing from metal plates has been accompanied by changes in trade practice, in cost, and in the introduction of machinery. Hitherto, zinc plates were all grained by hand. The coated plates, introduced since 1885, were in some cases grained by sand-blast; but when the great use of metal plates became apparent, an old form of stone-grinding machine was remodelled, and appeared as a mechanical graining machine [4]. This is a large, water-tight trough, supported upon spherical bearings or moved by cams, so that it executes a short circular movement, similar to the hand method of graining with a muller The plate is placed in the trough, and covered thickly with balls of wood, glass, or porcelain, upon which may be sifted the graining sand, and water sprinkled all over the whole. The motion of the trough is imitated to some extent by the balls, which travel very slowly, owing to their crowded condition, and by their motion press the sand upon the plate and grain it. The economy of this machine has made it indispensable to any large user of metal plates.

Lithographic Printing Machines. For printing from metal plates, practically all the printers' engineers in Great Britain, the United States, Germany, France, and Italy made excellent machines. The new conditions of printing from metal brought about the perfection of the damping apparatus, and introduced changes in the gearing of the inking-rollers. Indiarubber rollers were tried for these machines, and ultimately abandoned; the construction was made to meet the necessity of the closest register of colour-work; and in this direction many examples from the United States and Canada showed how perfect the machines had become.

The rotary principle had been attempted in 1842, and had gone through various stages of development in a spasmodic way all through the century. In 1886 it was placed upon a sound footing by T. Ruddiman Johnston's machine, and with numerous other machines from year to year it culminated in 1899 in the well-built rotary of the Aluminium Plate and Press Company of New York. Thenceforward the rotary principle was established, and was to see unheard-of adaptation.

At the Printing Trades Exhibition of 1904, George Mann & Co. showed a rotary machine for tinplate printing, which, as a novelty, was one of the most unexpected inventions; but it has gone on and has been successfully adopted by many printers The principle of the tinplate printing machine lies in the fact that the original metal plate is caused to print upon a rubber-covered cylinder, and this cylinder yields its impression to the tinplate which is brought into contact with it. Tinplate printing was not new in 1904; it had been in vogue in one way or another since 1875, and had passed through many stages of improvement. The principle of printing from an elastic surface had also been adopted in those earlier days; and there is little doubt that some printers had used such machines for printing upon thick pulp and other boards, on fabrics, and the like. But no one seems to have suggested using such a machine for printing upon thin papers in the ordinary course of business.

Offset Printing Process. Such an adaptation was conceived by Ira W. Rubel in the United States in 1906, as the result of a common incident in lithographic printing. He was watching printing in a machine, when the feeder failed to place a sheet of paper in position, and the impression was printed upon the cylinder. The next sheet of

paper received this impression upon its back from the cylinder, as well as on its front from the stone. But the impression on the back was interesting because it was so perfect, although printed upon the wrong, or rougher, side of the paper. It gave rise to contemplation, and during 1906 Rubel had a machine built to print by offset—that is, to introduce a rubber-covered roller to receive the first impression and transfer or set it off upon paper brought in contact with this rubber cylinder. To those outside the trade this might have appeared somewhat unnecessary, but in the trade the principle was soon recognised and appreciated. The largest amount of lithographic printing is the production of business letter-paper and similar commercial paper. In addition, there is a very large production of share certificates and similar company papers, all of which are executed upon hard papers, many of them hand-made. The printing upon these papers has always been difficult, especially when it is stipulated that the paper shall not be damped. It was in this direction alone that the offset method would prove of incalculable value, and it was for this class of work that it was first used. In fact, printers themselves were apt to say it was only applicable to that work. Time has proved to the contrary.

Advantages of the Offset Method. The new method opened a new channel for planographic printing. Hitherto, lithography had been unable to print upon the rough papers used in letterpress printing, but by this offset method it has become possible to print upon any surface and any thickness of paper. It has gone beyond the limits of letterpress printing, in the accomplished fact that fine photographic process-work can be printed equally well upon rough paper with a result so soft that it loses the mechanical cross-line or screen, and emerges into a collotype or photogravure effect. It has widened the range of lithographic work, and created a new phase of the process; and concurrently it has generated a public taste for the evenness of its products, which seldom have the appearance of being overloaded with ink.

For colour-work it has proved perfectly satisfactory, and has led printers' engineers into building machines of increased capacity, such as have not been possible in either flat-bed or direct rotary printing machines. Perhaps the greatest advantage of offset printing is in the increased speed. No machine is built with a lower capacity than 1500 per hour; the machine suitable for all classes of work can be run at 2500 per hour; and machines for some classes of work may be run at from 3000 to 6000 per hour by using an automatic feeder [12].

The application of the offset method to commercial printing, much of which is transferred from engraved plates, soon led to the production of tone engravings by the intaglio rather than the relief method, in order that transfers could be taken from the plates by lithographers, and transferred for offset printing. At the same time great attention was given to photography, to obtain direct tone photographic process-work upon the plates.

It may be said that every known method of printing has been tried by it, and in very few cases has it not fully justified the experiment. Some printers have used it for work usually printed by letterpress machines, because of its speed, coupled with the economy of lithographic transferring as compared with stereo- or electro-typing.

Offset Machines. The offset machines now in use are of three distinct types: (1) The American pattern in which the printed sheets are delivered low down, almost on the floor; (2) American and German machines where the delivery is direct from the printing cylinder upon a board raised about two feet from the floor; (3) British and German machines in which the delivery is high, and immediately under the inspection of the attendant [11]. Some British, French, and German machines have been built on the American type.

The machines are now being manufactured by Messrs. R. Hoe & Co., Walter Scott, Potter, Hall, Kellogg, and Harris in America; G. Mann & Co., Waite & Savill, Furnival & Co., and Linotype and Machinery Ltd. in Great Britain; Voirin in Paris; and by Albert, Mailänder, and the Vogtland Company in Germany. In addition, Messrs. Eyre & Co. of Manchester make the necessary parts whereby flat-bed machines may be converted into offset machines. Messrs. Ratcliff & Sons of Leeds make flat-bed offset machines, and convert similar machines. So great has been the adoption of the two latter machines that it has prevented a very extensive sale of the rotary offset machine in Great Britain; but in America the Harris [7-12] and Potter offset rotary machines have been largely adopted, and there are few firms without them. In Great Britain the Mann offset rotary [11] has been well patronised; so, too, has the Waite & Savill [6]. A few American machines have been installed.

In addition to the single-colour offset rotary, Messrs. Geo. Mann & Co. have made a two-colour machine, and a machine to print from the roll or web [9]. Voirin of Paris has made similar machines, and Albert of Frankenthal has made a two-colour machine. In all these machines, except the three in the third group, the plate cylinder, with its inking and damping apparatus is at the top. In the other three machines the plate cylinder is hung low, and the inking and damping are at a convenient level for easy inspection.

After these machines had been in use for some time, presses were constructed for reversing transfers and proving work for offset printing. Of these there are at least four—the Fuchs & Lang, the Mann, the Reverso, and the Wogden. The last-named is exceptional, as it is capable of use as a lithographic printing machine.

"Printex" Transfers. Of the photographic methods which have been introduced as aids to lithographers, the "Printex" takes a premier position. For economy it is customary to use large stones or plates, and transfer upon them a large number of the same subject, whether in black only or in colours. To set up the transfers accurately by hand a considerable amount of time and dexterity is necessary. It is to save this that the "Printex" method was invented. The process is photographic and mechanical. The photographic operation is by far the more important, and with the mechanism for its accomplishment constitutes the basis of the invention. A diapositive or transparency of the subject is made, and placed in a special camera. The design is focussed upon a large sheet of glass which has been sensitised. This glass is placed in a rigid frame which can be accurately moved horizontally or vertically any required distance. Therefore, when all adjustments have been made, a series of exposures is carried out at regular intervals all over the plate, and gives a negative plate. This is ultimately placed upon a sensitive zinc or aluminium plate, and by one exposure the whole series of the design is printed on the plate, thus making a printing-plate ready for printing in the machine.

The accuracy of the method has led to its application to the production of cylinders and plates in relief and in intaglio for postage-stamp printing.

True to Scale or Vandyke Process. In many cases where a few copies of a drawing, such as engineers' and architects' designs and plans, are required, the ordinary blue-print or ferro-prussiate copy is satisfactory. But when the quantity is large such method is too expensive, and can be displaced by the more permanent method practised by Vandyke—an Englishman, with long experience in a Government printing-office in India. Like other methods adopted for a single purpose, it has been found useful for other purposes in which copies are desired of any subject made up of lines or dots.

Somewhat similar in principle to blue-prints, it is worked out upon a negative basis in its early stages, but assumes the positive character in its final result. The method, though apparently simple, must be carried out with every care in each detail if a really good result be required.

The process is direct photography upon a metal plate, which can then be used to print any number of copies. Any line-drawing or print, which is upon paper, the back of which is perfectly clean, may be placed upon a sheet of sensitised zinc or aluminium, pressed into absolute contact in a strong photographic printing-frame or a pneumatic frame, and exposed to light. According to the thickness or opacity of the paper, the exposure will also vary. Its actual duration should be measured by an actinometer. The effect of the exposure will be that all the clear paper will be printed upon the sensitive film, and the drawing will not be printed—in the photographic sense. The plate may then be flooded with water to remove the sensitiser from the film not acted upon by light, and treated with an aniline colour solution which stains the remaining film darker than the lines of the subject, and proves whether the exposure has been sufficiently accurate to proceed further with the plate. The plate is then treated with weak ammonia, and, after drying, is soaked in water, where it is gently rubbed with cotton-wool to remove the unexposed film. The plate is dried, and rubbed carefully with pumice-powder, and finished with whiting. This cleans the plate where the drawing prevented actinic action.

The subject is next treated with a strong bituminous, greasy ink, and allowed to stand for an hour. The plate may then be treated with weak hydrochloric acid to dissolve the exposed film, thus leaving the subject covered with ink, to be treated as an original upon metal.

Direct Photo-lithography. Of all the attempts to produce originals directly upon stone or plate, none have given better results than the work of Frey, of Zürich. His method is largely a personal one, assisted by photography. The photograph—or a set of three-colour photographic negatives may be taken—is printed upon a series of sensitised stones or plates. The sensitive film is probably bituminous, and can be dissolved by suitable solvents. It is at this point that the art is applied, as, after the photograph is printed, the artist dissolves such parts as are not required for that particular colour-plate. All the colour-plates are made up by the same method, but in some cases large areas are dissolved, in order that the artist may add work of a particular character to help the production. Pictures executed in this manner are the most realistic imitations of water-colour drawings ever produced, especially when printed by the offset method upon Whatman or similar paper.

Rotary Photogravure. In the routine of the lithographer, he is called upon to print from engraved copperplates—aquatint or mezzotint plates, etchings and photogravure. It is not therefore out of place to add a short account of the latest form which photogravure has assumed. In the past, the popular conception of photogravure was based upon the method of Talbot and improved by Carl Klic. It is almost entirely a photographic process, as will be seen by reference to the description in the section devoted to Photo-Engraving. To assist in following the later development, that article should be perused.

It will be seen that to produce an intaglio plate from which prints can be taken it is necessary to retain a granulated surface on the plate, while the actual picture is sunk or etched into the plate through the interstices of the grain. For the true photogravure, which is printed by hand methods, a bituminous dust will create a satisfactory grain, but for machine printing it does not prove effective. In printing by machine, the picture is etched upon a copper cylinder, the cylinder revolves in a trough of very thin ink, and is scraped or shaved clean, upon the parts not carrying the picture, by a knife or docteur. The paper is brought into contact, and prints are obtained at 1000 to 3000 per hour.

To secure this result, the granulation of the surface of the cylinder must be most perfect, and is obtained by printing photographically a black cross-line screen of about 130 lines to the inch upon that carbon tissue which has upon it the final negative picture, and is to be fastened on the copper cylinder as a resist for the final etching into the cylinder. It is by this means that in Germany, as long ago as 1904, newspapers were illustrated by photogravure. Since 1910 the method has considerably increased, and several engineers have constructed suitable machines, the latest of which is a British-made machine which prints two colours on one side of the web, and one colour on the other side, at one operation. The actual German patent was revoked in July, 1914, and the method is now growing into great favour. From early in 1914 a Southend weekly paper has had the last page printed in photogravure—this printing taking place at the same time as and at the same speed as the printing of the letterpress matter on the remainder of the paper. Whole magazines have been printed in the same way, including the type-matter; a section of the "Illustrated London News" has been printed by it since the autumn of 1912; the SELF-EDUCATOR contains work by this method [see frontispiece to page 4085], and catalogues of the highest quality are specimens of such work.

Progress of the Lithographic Trade. In concluding this summary, it may be said that in the ordinary way of business the lithographic trade has greatly improved. This is largely due to the offset process, and the more perfect application of photography which this process has rendered possible.

The applications of planographic printing are both beautiful and numerous. The well-known oleographs of forty years ago, and their continuation at intervals during the later period, the artistic and fancy Christmas-cards, illustrated toy books, atlases, natural history plates, representations of objects of art (pottery, silver, iron, fabrics), catalogues, and artistic publications, owe their value and charm to this business, a craft which is not of an ephemeral character and is not an amateur one, but one which requires many years of steady application to learn and carry out successfully.

CHARLES HARRAP

The Methods of Ascertaining and Stating the Quantities of the Various Classes of Material and Labour in Building Work

THE QUANTITY SURVEYOR

QUANTITY surveying is a process in building enterprise which comes, in point of time, between the preparation of the drawings and specification by the architect and the making of an estimate by the builder. A bill of quantities purports to set out, in the terms usually employed in the building trade, the quantity of materials and labour which will have to be supplied, and, generally, the services which must be rendered in erecting and completing a particular building for which tenders are desired.

Qualifications. To make a successful quantity surveyor the qualities of character requisite are a love of accuracy and thoroughness and what may be termed intelligent doggedness; intellectually, a taste for analysis, for calculation, for construction, and for mechanical contrivance. The young man who hopes to attain his results by brilliant dashes has no place here.

The general education which must precede technical training includes clearness and neatness in writing—especially in the making of figures—the ability to write English with precision and distinctness, a thorough knowledge of arithmetic and mensuration, and a firm grasp of elementary mathematics, including plane and solid geometry—as taught at South Kensington—some familiarity with mechanical and—if possible—freehand drawing, and bookkeeping. With this equipment a lad of 16 or 17 will be ready to begin the study of the technical work of quantity surveying.

Squaring. Measurements in a quantity surveyor's office are calculated in duodecimals, and the first work he would there be put to is what is known as "squaring dimensions." An example follows:

EXAMPLE OF SQUARING DIMENSIONS

	31 0 24 0 6			12/	10 0 7 4 24		
		587 0	Excavate general surface not exceeding 6' 0" deep and throw out			16 11	Fir framed in floors
			and Fill earth into carts and cart away	1·2/2/	5 6 5 3	91 0	2" deal moulded casements, with cross bars and hung at bottom
	153 4 2 0						
	5 0	421 8	2 B in mortar	2·6/	14 6	145 0	4½" × 3" fir wrought all round and framed, rebated, and twice beaded frame
		9 10	Render float and set on brick walls	4·3/	3 7 2 8		
	4 0					66 10·8	1" steel
	8 0						
		37 8	Cube brickwork in mortar		3 2 1 4		
24	6 0					2 10·8	Planing on steel
2/3·7	No 5	144 0	Rough cut birdsmouth				
		100	Ends of timbers cut and pinned				

Of the three columns on the left hand side of the paper the middle one is for the actual measurements, or "dimensions," which are known as "cubes" (*i.e.*, solids), "supers" (*i.e.*, areas), "runs" (*i.e.*, lineal measurements), and "numbers." The column on the left is for "timesing" (*i.e.*, multiplying); in the column on the right are put down the results of the "squaring." The result is usually calculated to one place of duodecimals; if any remainder fall short of 6 it is neglected; if 6 or over, a unit is added. In some cases, as in measurements of steel, iron or copper, the squaring is carried to two places. The third item given above is a semicircle of 5 ft. diameter, its superficial area being set down in the third column. The next item represents a solid mass semicircular on plan and 6 ft. deep; in the third column is its cubical content. The process of "timesing" is as follows: "2/" means twice; "3/2/" means first multiplied by two and then by three, or six times; "1·3/2/" means multiplied by two, and then by three *plus* 1 (or four)—*i.e.*, 8 times. The figure "1" is said to be "dotted on"; "$3/\frac{2}{1}/$" means three times three, or nine times. The student will do well to practise squaring dimensions (which he can easily invent) until he becomes proficient.

Abstracting. The next process in the work is "abstracting," somewhat analogous to "posting" in bookkeeping from the day-book to the ledger, and consists in transferring the results of the "squaring," together with the descriptions of all the items on the columns of dimensions, to the sheets of abstract, at the same time arranging them under the various trades to which they belong, and in the order in which they are finally to appear in the bill. Abstract paper is usually ruled as shown in the illustration, the vertical lines being rather less than an inch apart. Sometimes these lines are made by folding the paper. The chief difficulty in abstracting is in the "setting-out"—that is, in judging of the amount of space to leave for the different items. It will be readily understood that quantities of the same item occur many times in different parts of the sheets of dimensions, and one of the objects of abstracting is to collect them so as to form one item in the bill. Example of abstracting:

EXAMPLE OF ABSTRACTING

Bricklayer.

Reduced Brickwork in Mortar

	Cube	1 B	1½ B
	420·0	100·0	60·2
	78·8	45·9	170·8
		1,740·2	39·7
	445·0	560·4	720·4
	50·6	880·5	970·0
	395·6	3,126·9	1,551·3
	44·3	570·10	445·3
	354·3	2,930·10	1,506·4
Less ½rt =		936·7	354·3
		1,873·3	1,872·3
		3,733·10 = 13 rods 106 feet.	

Plasterer.

	Cube	1 B	1½ B
	50·0	45·0	113·11
		120·6	40·10
		30·9	29·6
		240·7	270·0
		520·10	445·3

Joiner.

9" × 11" deal moulded skirting and backings

150 0 — Fitted ends

5 — Internal mitred

6 — External mitres

6· — Returned and mitred ends

2·

11" deal moulded and square fixed framing two panels high

50·0 — Extra on ditto for part formed as door, 2' 6" × 6' 6", including the requisite splayed and rounded fillets mitred round as stop and fixed with screws

4·

Less ½rt =

The only dimensions that sometimes undergo a change in their way to the abstract are those of brickwork. In the usual or "London" system of measurement, brickwork is reckoned in superficial "rods" (*i.e.*, 272 ft.), reduced to a thickness of 1½ brick, and the items are abstracted in a way to facilitate this. Thus 500 ft. super. of 2 B (*i.e.*, wall 2 bricks, or 18 in. thick) would be abstracted as 1,000.0 under the head of 1 B; 500.0 of 3 B, as 1,000.0 under 1½ B; 500.0 of 2½ B as 500.0 under 1 B, and 500.0 under 1½ B; 500.0 of 2¼ B as 500.0 under 1½ B, and 250.0 under 1½ B; and so on. When the columns have been added up, and the deductions subtracted, the total of 1B is "reduced" to 1½ B

by deducting one-third (or multiplying by two and dividing by three), the result is then added to the 1½ B, and the sum divided by 272. Expertness in abstracting can be attained only by practice. The following general maxims, however, may usefully be borne in mind. Do not be afraid to use plenty of paper. Be careful to put the figures exactly under those to which they will have to be added. Do not take any liberties with the dimensions. Abstract the descriptions precisely as they are given by the taker-off, and, above all, do not use any abbreviations of your own invention. Abstract all notes and memoranda as carefully as any of the dimensions. As each item is abstracted a vertical line is drawn through it on the sheet of dimensions. The abstracts are then checked, the items thereon being ticked in red, and the corresponding items in the dimensions cut through in red. This done, the abstracts are "made up"—that is, the columns of figures are cast, deductions abstracted, and then results brought into superficial yards, cubic yards, cwts., qrs., and lb., etc., as the case may be. This work, for the sake of clearness, is commonly done in violet and checked in red, or done in red and checked in black.

Billing. Billing consists in taking from the abstracts, when prepared as above described, the various items thereon and throwing them into the form of bills ready for pricing. The following is a usual order of bills. No. 1, Preliminary. This bill consists of general items not susceptible of measurement and not belonging to any particular trade, and yet important to be borne in mind as forming an element of cost—for example, provision of water for the works, sheds and latrines for workmen, office for the clerk of works, insurance from fire and making good after that or any other accident, keeping the building in repair for a stipulated time after completion, risks and expenses under the Employers' Liability and National Insurance Acts, and other matters extracted from the contract and the preliminary clauses of the specification.

No. 2, Excavator and Concretor; No. 3, Bricklayer and drains; No. 4, Mason; No. 5, Tiler (or Slater) and Slate Mason; No. 6, Carpenter; No. 7, Joiner and Ironmonger; No. 8, Plasterer; No. 9, Founder and Smith, Gasfitter (or Electric Lighting Engineer), Bellhanger, Hot-water Engineer; No. 10, Plumber; No. 11, Glazier; No. 12, Painter and Paperhanger; No. 13, Summary.

At the head of each bill are put the general clauses from the specification touching the labour and materials proper to the trade—for instance, the nature and quality of the bricks, stone, slates, timber, steel, etc., the composition of the concrete and of the mortar, the bond of the brickwork, the gauge of the slating and the like. Of the order of the items in the various bills it is not possible to give more than a general account. Suffice it to say that, usually, "cubes" come first, then "supers," "runs," and "numbers." Within these divisions the order followed is, generally speaking, that of increasing value.

Taking-off. We now come to "taking-off," or the measurement of builders' work from the drawings and specification prepared by the architect. Here it is that the chief work of the quantity surveyor is found, and on his excellence in this will his standing in his profession rest. During the whole of the time the student is engaged in the subordinate class of work already described he should keep his eye on the "taking-off" and lose no opportunity of qualifying himself for it, spending an evening or two every week in studying building construction at classes such as are held at the various polytechnics or under the Education Department, South Kensington. It has been said that in order to take-off properly a surveyor must understand every process in every trade. This is perhaps a slight, but only a slight, exaggeration. The student will do well, therefore, to keep his eyes open and observe any building work, however trivial, that may be going on, if it is only a carpenter putting in a sash-line or a plumber bending a pipe or wiping a joint. Every opportunity, too, should be seized of going over buildings in progress, especially while the workmen are there. True, much information may (and must) be got from books, but the student should make a point of *getting into contact with the work itself*, and should not be satisfied until he has seen an example of whatever he has read of in his studies. Failing this, he will find himself at an immediate disadvantage when he comes into contact with other surveyors, and especially with builders.

General Rules of Measurement. In the following pages it is assumed that the student has become familiar with building terms.

In measuring a length, always measure from left to right. In measuring a "super"—for example, a door—the first dimension taken should be the width, the second the height, and the item would be booked thus:

3 0		2″ deal moulded both sides,
7 0		four-panel door.

In measuring a "cube"—for instance, a stone—the first dimension taken is the length, the second the distance from front to back, and the third the height. This order should never be departed from. Walls, plastering, slating, etc., are measured as if the openings in them did not exist. These will be deducted later. In booking the dimensions care should be taken to avoid crowding. Not infrequently it is necessary to go back and insert a dimension, and a good rule is to leave room between every two dimensions for another. In writing the descriptions it is important to keep well clear of the line on the left, bearing in mind that the squaring has still to come. If any dimension is arrived at by calculation the process should be shown on the right-hand side of the column, thus:

		N 84 0
		E 43 0
		127 0
		Ddt. 10 6
		116 6
116 6		1½ B in cement. *North and East*
14 0		*walls ground floor to first.*

Generally state at the end of the description the situation of the work in question in the building. Read carefully through the specification before beginning to take off. Never put down an item that you do not yourself understand, or do not see how it is going to work, even if you can quote chapter and verse for it from the specification. The architect is entitled to expect you to consult him upon it. Settle your order of taking off, and having settled it, be exceedingly chary of departing from it even if another way seems less cumbrous in a particular case. It is often important to be able to go back, perhaps a year or two later, and follow a measurement without hesitation.

Order of Taking-off. Until some forty years ago it was the practice to take off each trade separately, but that custom is now quite out of date, and modern surveyors, broadly speaking,

measure not a *trade*, but a *thing*, whether it happens to involve one trade only, or several. The exceptions to this rule are joinery, plastering and painting. The following order of taking-off is recommended:

Excavation and concrete foundations; brickwork; damp-proof course; external facings; internal facings; formation of internal openings and recesses; fires; ventilation; external openings; floors; stone or concrete staircases; quarter partitions; roofs; eaves gutters and rain-water pipes; internal plumbing and water supply; drains; hot-water engineering; gasfitting; bellhanging; joinery; plastering and paperhanging; painting.

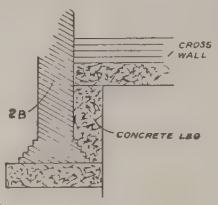
Excavation, Concrete and Walls. If the architect has not supplied a plan of the foundations it is often worth the surveyor's while to make one himself.

The first item of digging is sometimes a superficial one for removing the vegetable soil to a stated depth, say 10 in., but the general excavation is taken by the foot cube. If the contour of the site is irregular, an average depth may be got by a series of ordinates. When the "surface excavation"—to bring the level down to that of the concrete under the ground floor—has been taken, the excavation for the basement is measured, first to a depth of 6 ft., describing it as not exceeding 6 ft. deep, thence to a depth of 12 ft. (or less, as the case may be), describing it as "commencing at 6 ft. deep and not exceeding 12′ 0″ deep," and so on. The description must be worded so as to provide for any old foundations, roots of trees, drain-pipes, etc., that may be encountered. The excavation for the trenches should next be taken, first those below the basement, described as "Excavation for trenches commencing at basement level and not exceeding 6′ 0″ below same," and so on. Now, as to dealing with the earth excavated. In the case of, say, a mansion in a park, where the surplus earth can be easily disposed of, it will probably be sufficient to say of the excavation from the trenches "part returned filled in and rammed, the remainder wheeled, spread and levelled as directed." But usually, and in particular in large towns, where the removal of the earth often costs more than the digging, the portion carted away should be kept separate from that returned and filled in. A convenient way of doing this is first to measure all the earth taken from the trenches as returned and rammed, and then to take items of "deduct return and ram, and add cart away," thus:

150 0	Excavate trenches not exceeding 6′ 0″ deep, and throw out,
3 3	and
5 6	Return and ram around foundations.
150 0	Concrete as described,
3 3	and
2 0	Deduct return and ram,
	and
	Add fill and cart away.
150 0	Deduct return and ram,
1 11	and
9	Add cart away. *For footings.*
150 0	Ditto Ditto
1 2	And
2 9	Ditto *For wall.*

The area of the sides of the basement and of the trenches may now be measured for strutting and planking, keeping them separate. Next take the concrete foundations, using the dimensions of the trenches for this purpose, and not forgetting the "leg" required when a shallow trench abuts on a deep one [see sketch].

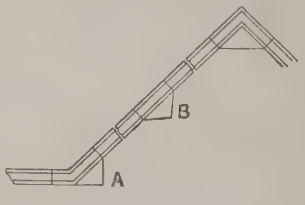
Next come the external walls, beginning with the footings, then the internal walls, chimney breasts and stacks, and piers. Great care is necessary to avoid missing any of the internal walls. A good plan is to take first all that run from left to right, and then all that go at right angles to these. The dimensions of the concrete for the external walls may sometimes be used for the brickwork. The walls may be conveniently taken floor by floor, but chimney breasts and stacks should be taken one by one, from bottom to top. The damp-proof course should next be taken from the measurements of the brickwork—as, for instance, all the one-brick walls collected and the total booked as a dimension by 9 in., and so on. Then the vertical asphalting on the outside of the basement walls next the earth as a "super" dimension, not forgetting to give the total length of the internal angles as "solid fillet at internal angle."



Any requisite steel girders, etc., to support walls on the upper floors should be taken with the brickwork, or noted to be taken later. The chimney breasts usually grow wider as they go up, and require 3 in. or 4 in. self-faced York stone corbels where they set off. Keep separate any brickwork in cement, also any brickwork hoisted more than 40 ft. above the ground-floor level, giving the stages 40 ft. to 60 ft., 60 ft. to 80 ft., and so on. All right angles are included in the price of the brickwork, but a lineal measurement is taken of all others—"birdsmouth," if internal angles; "squint quoin" if external.

External Facings—Chimneys. Measure the weathering on the tops of the chimney caps (super), next the cornices and neckings, etc., beginning with the projecting brickwork (super), and following with the cornice (lineal), as thus: "24.0 Extra on ordinary brickwork for red-brick moulded cornice, as sketch, five courses high, two square and oversailing, and three moulded." Number the mitres and returned ends, and measure the cement weathering on top. Take the general facing down to the roof line.

Copings. Take the brick copings (run), and describe as in the specification, separating the level from the raking and numbering the mitres, etc. Similarly, measure the stone coping, describing the material and the labour—for instance, 64 ft. run, 12 in. by 4 in. Rubbed Portland stone coping, weathered, moulded, and twice throated (as sketch), and set and pointed in cement; 20 ft. run, 12 in. by 4 in.; ditto raking to gables.



No. 4 external angles.

No. 2 internal angles.

No. 3 fair ends with returned and mitred moulding, etc.

No. 2 kneelers (as sketch A), 13 in. by 12 in. by 10 in. (labour and material).

No. 2 bonders (as sketch B), 10 in. by 12 in. by 10 in. (labour and material).

No. 1 apex stone, 16½ in. by 12 in. by 11 in. (labour and material).

Number the cramps as specified. Take fair raking cutting (run) to facings on both sides of the wall under the raking coping.

Cornices. The brick cornices, string courses, and so on will be measured as already described for the cornices of chimney stacks. If of stone, take them by the foot run, numbering the mitres, etc.—for example,

150 0		18 in. by 12 in. Portland stone cornice, rubbed, weathered, and moulded (as sketch), and set and joggle-jointed in cement.
No. 2		Stopped ends.
No. 6		External angles.
No. 2		Irregular angles.
No. 4		Internal angles.

General Facings. The general facings may now be taken, *between* the string courses, etc., but *over* all openings—*e.g.*,

N. elevation	44	6
E. elevation	30	0
S. elevation	20	0
At break 2/.9 =	1	6
	10	0
	14	6
W. elevation	30	0
	150	6

150 0		Extra on ordinary brickwork
28 6		for facings of best red Farehams, the joints raked out and afterwards neatly pointed with a weathered joint.

If the facings be of stone we should, instead, get an item such as the following:

150 6		Rubbed Portland stone ashlar,
28 6		average 6¾ in. on bed and setting and pointing as described.

Internal Facings. Measure the surfaces of the walls faced with brick; also the limewhiting or distempering, taking the description from the specification. In the case of glazed brick facing, give the run of the internal angles as "Extra for waste at internal angles."

Internal Openings. Begin on the lowest floor, and take the formation of all doorways, borrowed lights, archways, and recesses. Example of doorway:

3 0		1 B. deduct
7 0		*Between kitchen and passage.*
3 9		1 B. deduct
6		*For lintel.*
3 9		9-in. by 6-in. concrete lintel, including 2 in. by 2 in. by ¼ in. R.S.T. the whole length; also any requisite casing (brickwork deducted).
2/ No. 6		Extra on brickwork for concrete fixing bricks, 9 in. by 4½ in. by 3 in.
3 9		3-in. tooled York threshold,
9		edges jointed, and bedding in cement.
No. 2		Ends ditto, cut and pinned in cement.

Some surveyors here follow with the joiner's work for the opening.

If, instead of a lintel, we have an arch, we get:

3 2		Centring to segmental arch.
9		
No. 1		Extra labour and waste and cement for segmental arch in cement, 3 ft. span, 1 B. on soffit, 1 B. high.

Fires. Example of measurement of a fireplace.

3 0		
3 0		1½ B. deduct.
No. 1		Extra to segmental arch 3 ft. span, 1 B. × 1 B. a.b. (a.b. means "as before").
5 0		2¼ in. × ⅜ in. wrought-iron chimney bar, caulked and cambered and building in by bricklayer.
3 0		
1 2		2½-in. York tooled hearth, edges jointed, and bedding in mortar.
4 6		*Back.*
1 6		2½-in. ditto, rubbed ditto.
		Front.
4 6		Half-brick in cement trimmer
1 8		arch, and levelling in fine concrete for hearth, and centring trimmer arches.
4 6		Skewback cutting.
4 6		4½-in. by 2½-in. deal feather-edged springer.
No. 1		Filleting soffit of trimmer arch for lathing to.
No. 1		Slow-combustion stove, p.c. £3, and add setting same with the requisite bricks in mortar, firebricks, and fireclay.
No. 1		Rendering in lime and hair mortar to backs of fireplaces.
No. 1		Flue 30 ft. long, parged with cow-dung parge, and cored out at completion.
No. 1		Red terra-cotta chimney-pot, 2 ft. 6 in. high, and setting and flaunching in cement.
No. 1		Chimney-piece, p.c. £4, and add fixing in best manner with the necessary galvanised iron cramps, dowels, and cement, etc.
No. 2		Notching 2½-in. York hearth for jambs of chimney-piece.
4 0		
3 6		Deduct render float and set walls, and Deduct paper at 3s. per piece.
No. 1		Making good in Parian cement to plastering around chimney-piece.

The void in the case of flues (up to 14 in. by 14 in.) is not deducted. It is left to pay for the forming of the flue.

Ventilation. Take, first, all the foul-air extracts, and then the fresh-air inlets. Number the gratings, etc., and fixing, taking the descriptions from the specification.

No. 1. 14 in. by 9 in. cast iron galvanised air grating of approved pattern and building in, including forming opening in 1½ B wall, finished all round with ¾ in. Portland cement trowelled smooth, also the requisite 3 in. tooled York lintel.

The ventilators in the roof are usually taken with the roof.

External Openings. First deduct the brickwork, then take the work on the inside and afterwards that on the outside of the wall.

Example:

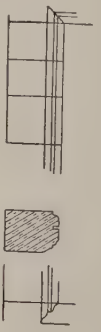
2/	4 6 6 3	1 B deduct.
		Night nursery windows (2).
2/	3 9 6 0	½ B deduct
2/	5 3 9	1 B deduct *For lintel.*
2/	5 3	9 in. by 9 in. concrete lintel, etc., a. b.
2/ 2/	No 4	Concrete fixing bricks a. b. 2/4 6 = 9 0 2/6 3 = 12 6 21 6
2/	No. 1	Window frame 21 ft. 6 in., around bedded in lime and hair and pointed in cement, the sill bedded in white lead.
2/	3 11	Centring to 4½ in. segmental soffit.
2/	3 11 4½	Extra on brickwork for red rubbed and gauged arch in T.L.B., rubbers set in cement and raked out and pointed to match the general facings.
2/	4 2	Ditto, and deduct red facings a. b.
2/ 2/	9	Skewback cutting to facings (at ends of arch).
2/	4 4	Circular cutting to facings (over arch).
2/	4 2	11 in. by 6 in. rubbed Portland stone window - sill, sunk, weathered moulded, throated, and grooved for iron tongue, and setting in cement (as sketch in next column).
2/	No. 2	Fair ends with moulding returned and mitred and stoppings to weathering, etc.
2/	No. 2	Ends of sill cut and pinned to facings.
2/	No. 1	Sill bedded hollow and made up and pointed at completion.
2/ 2/	4½ 6 0	Red facings as before. *Reveals* 6 0 6 6 6
2/	3 9 6 6	Deduct facings as before.

Some surveyors here follow with the joiners' work, etc., of the window.

The external openings should be taken floor by floor, beginning at the bottom and sometimes front by front.

Measurement of Stonework. In the foregoing instance the facings are assumed to be of brick. When, however, the facings of the front or the dressings of the openings are of stone, the measurement of the work on the outside is modified accordingly. It may be convenient at this point, therefore, to deal with the mode of measuring stonework, of which some general account may here be given, though the matter is too complicated to be explained with completeness. All stones not more than 3 in. thick are measured "super." Copings, cornices, string courses, plinth courses, are commonly taken by the foot run, with a sketch of the section, the mitres, etc., being numbered. Sometimes the stones are "cubed up" and described, being classified under several heads, as "cube Portland stone and all labours in plain string courses"; "Do. in moulded do. and cornices"; "Do. in moulded and rebated jambs of doors and windows," etc., accompanied by sketches illustrating the character of the work.

The most scientific mode, however, is to take the stone and the labours upon it separately. The only labour included in the price per foot cube is that needed to saw or draft it to its size, and to hoist and set it. First the size is taken as the smallest imaginary rectangular cube that would contain the finished stone, and if any particular stone is longer than is usual (generally 6 ft. and over), it is kept separate and called "scantling." The heading of the mason's bill should state that "the stone is measured net as set, including preliminary labours." The following are recognised labours taken by the foot super. "Back," the labour on the back of the stone, where it comes into contact with other material—as brickwork; "bed," the labour on the horizontal surfaces above and below coming in contact with stone or other material; "joint," that on the similar vertical faces at right angles to the front face (these are usually added together, the quantity halved, and described as "one face measured for two"); "sunk bed and joint," similar labour to bed and joint, but not rectangular with the adjacent faces, or rebated—as the joints of the voussoir of an arch or the sinking for a door frame (the last-named labour is sometimes kept separate); "circular bed and joint," the labour when convex as at the top of a voussoir; "circular sunk bed and joint," that where concave, as at the bottom of a voussoir when not exposed; "plain work," the labour on the exposed plain surface; "sunk work," that similar to sunk joint, but exposed, as the weathering on the top of a sill. Where the sinking cannot be worked without impediment (or worked "through"), as in a rebate on the outside of a window head, it is



termed "sunk work stopped." This applies also to other labours. "Circular work" is the face labour to convex surfaces—as to the shafts of columns; "circular sunk work," the like to concave surfaces, as to the soffits of arch stones; "circular circular work," the labour to the face when circular both ways, as to the outside of a dome; "sunk work circular circular," that to the inside of a dome; "moulded work" is measured over the whole surface as by a fine string; "moulded work circular continuous," as to the moulded base of a column. The following are taken by the foot run: chamfers up to 3 in. wide, mouldings up to 6 in. girth, groove, throat (*i.e.*, hollow groove), joggle, and the like; stopped ends, mitres, mortises, perforations, and so on, are numbered. Examples:

2/	1 2		Cube Portland stone and hoisting and setting as described. (*Six stones.*) *Jambs of window, south of library.* [See sketch.]
	10		
	5 2		
2/6/	1 2		Bed (one face measured for two).
	10		
		1 2	
2/	2 0	10	Half joint.
	5 2		
		2 0	
2/	1 4	10	Plain work
	5 2	6	
		1 4	
2/	1 5		
	5 2		Moulded work.
2/	5 2		Moulding 4in. girth.
2/	5 2		Groove for iron casement.

Reinforced Concrete. Before we proceed to deal in detail with floors, partitions, roofs, and other parts of a building, we may consider for a moment a new factor in modern building which the quantity surveyor will have to watch very closely. We refer to the use of reinforced concrete, of which the modern practice has been treated in the pages in the course on BUILDING. This class of work is still in its infancy, and considerable developments may be expected, which may result in modifying the mode of measurement in the following paragraph. However, we have set out what is generally accepted at the present time (1915) as the correct method of calculation.

Begin in each case with a description of the piece of work (*e.g.*, pillar, beam, or floor) about to be measured. Then take the net measurement in the same manner as for other work, and express the result as regards concrete in cubic feet, casing (or "false work," or "form work") in superficial feet, and steel in pounds. The measurement of the casing represents only the surface actually touching the concrete. The steel-work should be divided into classes (*e.g.*, bars, stirrups, meshwork, and hooping), the smaller bars (say, under ½ in. diameter) being kept separate, as also those over 30 ft. long. The work in each storey should be kept by itself, and the height stated. Further, each kind of work, as floors, roofs, beams, etc., should be set out in the bill of quantities separately, with the concrete, steel, and casing involved in its construction. The usual method of collecting the work under the head of trades is not followed in this case.

Floors. First take the "hard" floors, then the timber floors. Begin with the basement. Take any requisite hard core (super), describing the thickness, "well rammed and levelled for pavings," the concrete bed, the cement flooring, and the tile or other pavings, to the last-named of which, if the plan be irregular, take a "run" of "raking cutting and waste." To the upper floors take any cast-iron or steel columns or stanchions, girders and steel joists. Cast-iron columns are measured up in detail (super) as metal of such and such thickness, weighed out, 5 per cent. being added for featherings, and billed as:

Cwt. qrs. lb.	
128 2 14	In No. 6 cast-iron columns and hoisting and fixing by bricklayer at first-floor level.
	No. 1 pattern to cast-iron column 9½ in. mean diameter, 13 ft. high, 1½ in. metal, with moulded and bracketed cap and base and moulded necking.

Cast-iron stanchions are taken similarly. Steel joists are taken by the foot run, and weighted out, those over 16 in. deep being kept separate. Compound girders are measured up in detail, and kept separate, with description. This is also the case with riveted plate girders. In the last-mentioned case a percentage is usually added for rivet heads (from 2 per cent. to 5 per cent.). The shanks of the rivets take the place of the holes in the metal.

Connections of girders should be numbered and described. The steel-work of a floor having been taken, next measure the flat-boarded centering, the concrete—giving the thickness—the cement floating, etc., as before described. The timber floors now follow, beginning with the sleeper walls, etc., and the sleepers, plates, and ground joists (cubed up and described as "fir and labour in sleepers and ground joists"). To the upper floors, take any steel girders, and then similarly measure the joists as "fir framed in floors." Take the ends built in, and any stone or iron corbels next flues. Take the herring-bone strutting by the foot run. Measure any sound boarding and pugging over the whole area of the floors, and add to the description "joists measured in."

Slab Partitions. Measure these net as fixed, and describe the method of fixing. Where of irregular shape, take cutting and waste by the foot run. Take pinning up to under side of floors similarly. Enumerate and describe forming door and other openings.

Quarter Partitions. Take each piece of timber by the foot cube, and describe as "fir framed in quarter partitions." Keep separate any that are "trussed," and describe the latter as "fir framed in trussed partitions." Measure the horizontal timbers first, then the vertical, then the raking. Measure the straps by the foot run, and describe as "wrought iron in straps, forged as required, including perforations and fixing by carpenter." Number the bolts.

Staircases. Here follow the stone or concrete stairs, the steps being taken by the foot run by 14 in. by 7 in., or whatever may be the extreme size, and the material, finish, and form—as whether square or spandril—stated. The labour to the ends is numbered as "fair ends," or "fair ends with moulding returned and mitred." The ends cut and pinned are also numbered. Winders are numbered and described, the extreme dimensions being given, with sketches. Next take the landings by the foot super; similarly, the labour on the edges by the foot run, as also the "edge cut and pinned to brickwork."

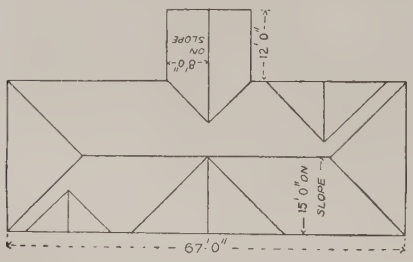
Number the newels and balusters, and the mortises and lead for them. Take also here the handrails, whether of metal or of wood, by the foot run, stating if "ramped" (curved in a vertical plane), "circular level" (curved on the horizontal plane), or "wreathed" (curved in two planes, as at the turn round a well hole). If the handrail be of wood, take at each joint a "heading joint and wrought-iron handrail screw, the heads, etc., let in and pelleted"—that is, concealed with wood pellets let in.

Roofs. If the architect does not supply a roof plan, it is worth while to make one yourself, or get one made. First, take the roof trusses, measuring by the foot cube each timber separately, thus: tie-beam, principals, king-post, struts; and describing as "fir-framed in roof trusses." Number the cleats for purlins, also the cast-iron shoes and heads, giving the weights and stating how many patterns will be required. Take the straps and bolts as already directed for partitions, and number the wedges and cotters, giving the weight. Take also the stone templates and heels of roof truss cut and pinned.

If the trusses be of steel, each piece should be measured in detail, and the whole reduced to weight. The item would then appear in the bill somewhat as follows:

Cwt.	qrs.	lb.	
244	1	7	In No. 7 steel riveted **roof trusses**, 59 ft. span, 15 ft. rise, of 4 in. × 4 in. angle as principals, $1\frac{1}{4}$ in. and $2\frac{1}{8}$ in. diameter tie rods, $2\frac{1}{2}$ in. × $\frac{1}{2}$ in., $3\frac{1}{2}$ in. × $\frac{1}{2}$ in., and 1 in. diameter bar as struts, etc., $\frac{5}{8}$ in. connecting plates, and all fitting, forgings, and cutting, rivets and bolts and holes, and hoisting and fixing by bricklayer, the apex 54 ft. above ground-floor level.

Measure the superficial area of the slating (or tiling) with the deal battens for same, and roof boarding and felt. If all the slopes are of the same pitch, the hips and valleys do not affect the area.



The area of this roof is taken in two dimensions, thus:

2/	67	0	Slating as described,
	15	0	and
2/	12	0	2 in. × $\frac{3}{4}$ in. deal battens
	8	0	spaced for countess slating and well nailed;
			and
			$\frac{3}{4}$ in. deal roof boarding, English cut, closely jointed, and all splays, notchings, etc., and well nailing,
			and
			felt as described, well nailed with clouts, and including laps (measured net, as seen).

Collect the total length of the eaves thus:

			2/	25	6 = 51 0
					27 0
			2/	12	0 = 24 0
					2 6
					3 6
					20 6
135	3		Extra labour and materials to slating at eaves		3 6
					3 3
					135 3

From the length of the eaves may now be taken the eaves fillet at eaves (run), or eaves board (super.), and the plate may be calculated; the roof plate (cube) next, and other horizontal timbers should be taken, as purlins, ridge-rafters, and slate or other ridges with a run of labour to top edge of slating; then the rafters and the ceiling joists (cube), the extra labour and material to slate verge (run), and the deal tilter thereto, the deal tilter and a run of square abutment on slating next gable walls, etc., and the lead soakers and flashings to make watertight connection between the edge of the slate roof and the wall. Lead soakers (super and weighted) are of 4 lb. lead, one to each course of slates (or tiles), lying 4 in. under same, and going 4 in. up the walls; the length should equal the gauge of the slating, plus the lap, plus 1 in.

Number them for fixing by the slater. For secret gutters, about 13 in. of 5-lb. lead is required. Next, 5-lb. lead stepped flashings, 6 in. wide, as cover (super and weighted). Lastly, the running length for lead wedging and for raking out joints of brickwork and pointing in cement to stepped flashings. All lead work is measured strictly net, with no allowance whatever for waste.

To chimney stacks take the deduction of rafters and the addition of the trimmers, etc., also the deduction of the slating, etc. Measure the square abutment of slating down the slopes and the lead work, etc., as to gables; at bottom a 5 lb. lead apron, 12 in. wide, and a run of top edge of slating. At top a lead gutter 8 in. wide. Assuming that the stack is three bricks thick, etc., the gutter is measured thus;

2 3		
8		$1\frac{1}{4}$ in. deal gutter boards and framed bearers.
No. 1		Short length of 2 in. deal rounded roll (across the gutter in the middle).
No. 2		Small 1 in. deal gussets, prepared one side for lead, and fitted and fixed at ends of gutters.
		ft. in.
		2 3
		Extra for roll 8
		At each end 2/.9 = 1 6
		4 5
		ft. in.
		Flat of gutter 8
		Against brickwork 6
		Up slope 1 0
		2 2
4 5		
2 2		6-lb. lead and labour laying in gutters.

No. 2			Ends of roll bossed 2 3 2/.6 = 1 0 3 3
3 3 6			5 lb. lead and labour laying as flashings.
3 3			Lead wedging to flashings, and Rake out and point flashings.
2 3			Large feather-edged eaves fillet, and Extra to slate eaves a.b.

Next, take the hips and valleys, first the timbers (cube), then the length by 6 in. of roof boarding for cuttings, also the length for the slate hips and for cutting and waste on slating. Number the labours at the ends of the hips and the hip hooks at the foot. For a lead valley, super up the 1¼ in. valley board, "splayed and fitted," run the tilter on each side, and super up the lead, the length plus 6 in. at each end, and 6 in. for each lap, by (say) 1 ft. 6 in. wide.

Take the gutters next parapets, etc., in the manner already described, but measure the rolls and drips by the foot run, and at each 2 in. drip, allow 8 in. extra of lead. Take the cesspools thus:

No. 1			1¼ in. deal dovetailed cesspool, 10 in. × 10 in., and 5 in. deep (all in clear), holed, fitted, and rebated for cover.

Super up the lead lining, and number the "extra labour, etc., dressing and copper nailing lead in cesspool," the copper cover, the lead socket pipe to carry the water to the rain-water head outside, and the hole through the wall. All the cube timber in the foregoing is described as "fir-framed in roofs." Another way is first to measure all the timbers, boarding, etc., as above, and afterwards the slating and lead work. Note particularly that the lead work of a gutter should always be carried up the slope of the roof to a vertical height of 6 in. above the sole of the gutter.

Eaves Gutters, and Rain-water Pipes. These are taken by the foot run, now generally measured net, excepting to small breaks, and around pilasters, etc. (which are numbered), the size and description and mode of fixing being given, as thus:

98 0 5 in. by 4 in. cast iron moulded eaves gutter (No. 20 in So and So's list), with rebated joints made up in red lead and two bolts to each joint, and strongly screwing to deal fascia and bedding and pointing in cement on brick cornice, including all cuttings and waste (measured net). The stopped ends, angles, outlets, and covers for same are numbered. In the case of rain-water pipes the swan-neck bends should be numbered, the girth given, and the number of patterns required stated.

Internal Plumbing and Water Supply. It is convenient to include in the heading of this bill a table of the weights per yard run of the lead pipes, the pipes being classified as "waste," "service," and "main." The size of a pipe is the diameter of its bore. The price per foot run fixed includes running joints, wall-hooks or tacks, also bends, unless the pipe is 2 in. or over, in which case the bends must be numbered in addition. Number the soldered ends, also the "branch" joints, stating the size of the pipe—as in the following example:

No. 2			Extra soldered joints to 1 in. lead pipe, or,
No. 2			Soldered joints of ¾ in. and 1 in. lead pipes.

The joints to taps and unions are included with them. Lengths of pipe under 2ft. 6 in. are numbered, the number of bends in each being stated.

Fittings and Wastes. Begin with the w.c. on the top floor. Number the apparatus, giving description and including fixing and all unions and joints. Next take the soil pipe down to the drain and connect thereto, also up, as ventilator, and finish with cap, and take the hole through the wall. Take the water-waste preventer, the overflow pipe from it, and the hole through the wall, the flushing pipe and connection to pan. Similarly, take all other w.c.'s, urinals, etc., discharging into this soil pipe. Take the anti-syphonage pipes. Sinks, urinals, lavatories, and baths and their wastes are measured similarly. Care should be used to take the traps if they are not included in the description of the fittings—for instance, to the lavatories. With the fittings it is convenient to measure any draining-boards, cupboards, etc., connected therewith.

Cisterns and Pipes. Cisterns are usually of galvanised wrought iron. Describe the capacity—*e.g.*, 300 gallons—the thickness of the metal, and the height to which hoisted. If the situation will not allow of a stock size being used, give the exact dimensions. Take any fir or steel bearers, the lead or zinc safe under and waste pipe from same, and the deal cover. Next, take the "warning pipe." If this passes through the roof, take a slater's number item of "perforation" through slated roof for pipe passing through, and making good, and plumber's item for a set of 5-lb. lead flashings soldered on. With each pipe that leaves the cistern take the connection thereto—as:

No. 1			Perforation in galvanised iron cistern for 1½-in. union.
No. 1			1½-in. brass boiler-screw union and fly nuts and 7-lb. lead washers to iron cistern, and soldered joint to lead pipe.

From the cistern take the service pipes to the various fittings (except, perhaps, the sinks, which are now usually supplied from the "rising main"). Measure the chief pipe from the cistern on to the point where it ends, and number the soldered end or tap which finishes it. If, in its course, the pipe diminishes—say, from 1½ in. to 1¼ in.—take at that point a "1½ in. extra soldered joint." Next take the stopcock on it near the cistern; then the first pipe that branches from it to its end, with all its taps and branches, complete. That branch being exhausted, pass down the main pipe till you come to the next branch; exhaust that in like manner, and so on. Having completed the pipes from the cistern (termed "services"), take the "supply pipe"—that is, the pipe from the main in the road up to the cistern—and the ballcock at the end of it. Then the stopcock near the beginning, and next, any branches to sinks, etc. If there are two or more cisterns, take one and all the pipes from it before touching the other. If iron pipes are used, the mode of measurement is much the same as in the case of lead. With the pipes take all pipe-casings (run), also holes through walls and chases.

The hot-water supply, gasfitter, bellhanger, lifts, speaking-tubes, and electric lighting follow here, and are usually dealt with by provisional sums of money.

Drains. Stoneware drains are usually measured to multiples of 2 ft.; thus a measurement of 46 ft. 10 in. is booked as 48 ft. Cast-iron drains are measured net or to 1 ft. lengths. The rule followed should be stated. Begin with the gully at the point of the drain farthest from the outfall, number and describe it, with the excavation and concrete and setting, and take the stone cover. Next take the drain therefrom to the first chamber, describing the size of the pipe, how jointed, and the average depth of the trench and any concrete under or around it. Count up all bends, junctions, etc. Complete the drains that go into this pipe and this chamber, and then take the chamber. Next take the pipe from this chamber into the next, and all branches, with their gulleys, etc., and so on. Finally the pipe from the last chamber up to the sewer in road and connection therewith. Take any ventilating pipes.

Joiner's Work. Measure the floor-boards (super), describing the material, thickness, etc. If any edge of a floor is not square with the others, take the length by 3 in. for waste. With the skirtings, chair rails, dados, and wall-linings, take the grounds, separating those that are plugged or fixed with wall-hooks across flues. Number the mitres, etc., in skirtings, and chair rails, and to dados, etc., take them by the foot run.

Staircases. First take the newels (run), numbering the caps and pendants; next the wall-strings and outer-strings (run), separating the "ramped" and "wreathed," etc. [see page 5738], then the steps, for which take the length from left to right *plus* 1″ at each end (housing). This dimension, multiplied by the width of the tread and the height of the riser added together is the measurement of a step, and should be booked thus:

Tread 11
Riser 6
1 5

3 3 1 5		1¼ in. deal treads with moulded nosing and 1 in. risers, tongued together, glued, blocked and bracketed on and including two strong fir carriages and prepared for cut strings—(if the ends are visible, or for close strings if otherwise). Note that if *a* is the width of the tread and *b* the height of the riser, *a* plus 2*b* should usually equal 23 in.

Winders are measured net, thus:

3 3 3 3 10 9 7		Ditto in winders and risers measured net 6 — 3 3 1 — 3 9 7 — 3 9 — 10 9

If the bottom step is longer and with a semicircular end measure it the extreme length and take in addition an item:

No. 1		Extra on treads and risers as before for semicircular end with solid block and veneered front to riser without heading joint (say) 4 ft. 6 in. girth.

Take housing or returned and mitred ends of the steps; the handrail [see page 5738], number and describe the balusters, stating how fixed at ends, and measure the lathing and plastering to the soffits. Super up and describe the landings, including bearers.

Windows. Measure sashes and cased frames, the extreme width by the extreme height, and give the description from the specification. If the head is (say) segmental, add the words "with segmental head, measured square." The price per foot for this work includes the usual splayed edge on the bottom rail and the splayed edges of the meeting rails. Any further labours are extra and must be taken by the foot run. Mention in the description if weighted for plate glass, also if in two or more lights, with cased mullions. Take the run of the galvanised iron tongue and groove in sill and number the sash fasteners and other ironmongery. Take the glass, bearing in mind that parts of inches are counted as full inches; thus, 11¼ in. is 1 ft. If the glass is of irregular shape, measure the extreme size and describe as "cut to shapes." Take the linings, whether of wood or cement (super if over 4 in. wide), arch traves and grounds (run) the window board (super) and the deduction of plastering and paper. Casements and solid frames are taken similarly but in detail, the casements being supered and described as "fixed," "hung at side," or as the case may be, and each piece composing the frame taken by the foot run and the labours on it described.

Doors are measured by the foot super, the width by the height, and described as:

3 0 7 0		2 in. deal four panel moulded both sides door.

"Moulded and square" means moulded one side and square the other. If a door is glazed, describe it as (say) "rebated and moulded on solid, and prepared for glass," take the run of the small beads as stop for glass (including mitres) and measure the glass.

Next take the linings (super) or the solid frames (run) and the hinges, locks and other ironmongery and architraves. Deduct the plastering and paper. In the case of swing doors measure the run of the rounded edges similarly. Space does not permit of entering into the measurement of screens and cupboards and other fittings, but the student will find little difficulty in adapting the information given above to joiner's work of this kind.

Plastering. Measure the ceilings (super), taking the description from the specification, and mentioning if panelled or coved. Take any ceiling mouldings (run), giving the girth and numbering all mitres, etc. Next the cornices, super if 12 in. girth or over, if not, by the foot run, giving the girth. Number all mitres, etc., giving the average girth of the moulding to which they belong. Bear in mind the "core" for the cornices. The smaller cornices may be in solid plaster, but for the larger ones some "bringing-out" is required, oversailed courses of brickwork, if practicable, and, failing these, deal framed bracketing (super) of about two-thirds the girth of the cornice. Wall surfaces are taken super, the same dimension serving for the plastering and for the papering.

Painting. Painting is usually measured for the most part from the sheets of dimensions after the abstracting and checking have been done. This system has the advantage of giving the surveyor a final look through his dimensions, often invaluable. Measurements in painting are taken (super) "wherever the brush goes," and are classified according to the number of coats, kind of finish, whether in two or more tints, etc. Any work that will have to be done off ladders should be given separately. The measurement of executed work follows the lines of the "taking off" from drawings.

F. H. A. HARDCASTLE

Advertising is True Economy for Buyer and Seller. The Psychology of Advertising. Planning a Campaign. Newspaper Advertising.

THE PRINCIPLES OF ADVERTISING

THERE is nothing essentially modern in advertising. As Mr. Herbert N. Casson has well said, it is like electricity. "It has always been in the world, but nobody knew of it or tried to organise it until a very few years ago. Considered as a profession, it is new; but considered as a force, it is as old as the human race." And certainly for men with imagination and initiative and industry—the three must be combined—advertising does provide a lucrative and exceedingly absorbing profession.

The Most Economical Method of Selling. The definitions of advertising are legion, from the bald statement of the dictionary that it is "the art or practice of bringing one's business into public notice," to the lengthy disquisitions of some of the so-called consultants glorifying it into a science almost as exact as mathematics. We are not concerned here, however, with mere definitions, but rather with facts; and there is undoubted truth in the statement that advertising is the most economical method of selling goods that has yet been devised. This may seem a hard saying to those who have always thought of the advertising department of a business as the great spending, or even spendthrift, department, but its truth may be illustrated in this way.

A merchant or manufacturer producing a household or personal commodity, such, for example, as boots or shoes, takes a page in the "Daily Mirror," or some other large newspaper of proved value, at a cost ranging from £150 to £300, according to the particular page selected. Of the million or more readers who see the announcement, several tens of thousands reply, and eight or ten thousand eventually become purchasers, mostly through the post.

But the sales do not stop with the ten thousand referred to. The majority of these purchasers, being satisfied with their purchases, buy again, and may become regular customers without the need of further advertising expenditure for them. Now, as the purchasers are living all over the country, and the business is done by post, it is absolutely necessary for the firm to go to the prospective customers. They will not pass the merchant's shop and be attracted by his window display. To take ten thousand orders from all parts of the country would require a great number of travellers and an enormous expenditure compared with that involved in the page advertisement. A little consideration and thought will show that in no other way could the goods be sold so economically as by the advertising.

Examples of Advertising that Pays. This is only one of many illustrations that might be given; and the statement about advertising being the cheapest method of selling goods yet devised is proved to be true by the fact that it is adopted by all firms worthy of the name. More than this, practically everybody now advertises. A man is presented by his wife with a son, and so proud is he of the fact that he desires all his friends to know it. How does he set to work? Does he write a letter round to each? No; he advertises in the newspapers, and saves himself endless time and trouble.

A lady loses a gold bracelet presented to her by her husband. Does she walk about the streets day after day, asking every person she meets if he has seen her missing jewel? No; she has a bill printed and stuck up in the shop windows of the district, asking that the finder will bring her bracelet to a certain address, and if it has not been wilfully stolen she will probably get it back. She simply follows the method of an Egyptian advertiser of three thousand years ago, who, when his slave ran away, had a "Lost, Stolen, or Strayed" announcement, made out on papyrus, exhibited in prominent places. We know this, because the papyrus is now to be seen in the British Museum.

The biggest and best army that has ever been recruited on the voluntary principle—one so great that the possibility of success would have been regarded as ridiculous before it was actually accomplished—was recruited, as we know, by means of a great advertising campaign.

Why Advertising is True Economy. Advertising is true economy. Right at the outset it must be fully understood that advertising is not simply an expense. It is true economy, not merely for the seller of goods, but for the buyer. Were it not for advertising, we could never buy soap, cycles, jam, cigarettes, cocoa, books, boot polish, salt, mustard, and a thousand other things of everyday necessity as cheaply as we do now. We have already seen the economy to the seller. Put briefly, the economy to the buyer comes somewhat in this way: a factory has a plant put down to turn out, say, cycles. A certain sum is required weekly to keep the factory going, this sum being wages plus establishment charges—rent, light, power, administration, and so on. (We are not now considering raw material.) By judicious advertising of the right kind, twice the number of cycles now being turned out can be sold.

The advertising is carried out, the increased demand is created, orders come in, and double the number is sold. But in order to make twice the number of cycles the plant does not have to be doubled, nor even do we need twice the number of workers, and certainly the premises do not require doubling, even if they require slight enlargement. The establishment charges being increased so little comparatively, and spread over 2000 cycles instead of over 1000, are naturally greatly reduced per cycle. To a less extent this is true of the wages; and as a result a less price can be charged to the buyer, and yet prove more remunerative to the seller than the higher price per cycle charged when half the number was being produced. This is just a very crude and brief outline of the principle upon which advertising works, and it shows that the idea of the ignorant—that because a firm spends thousands a year on its advertising, therefore the consumer must pay more for his goods—is a fallacy, reasonable though it seems on first consideration.

The Varied Nature of Advertising. So varied are the forms of advertising, and so wide its ramifications, that to give anything like an exhaustive account of all its activities would occupy quite a library of volumes. To mention only a few of the recognised media of advertising which are used by up-to-date and live firms: there are newspapers, daily and weekly, monthly magazines and annuals; show-cards, price-lists and catalogues, descriptive booklets, tramcars, omnibuses, railway stations, and tube trains, electric signs, cinematograph screens and films, theatre and concert programmes, exhibitions, handbills, calendars, lantern slides and lectures, tram tickets, stamp books, novelties, fancy costumes for balls, shop demonstrations, window displays, picture postcards, samples, and so on. With such a multiplicity of media, it is obvious that, before any advertising can be done, something in the nature of a plan of campaign must be thought out, even if it is not dignified with that name.

The Psychology of Advertising. But if we are going to choose our scheme and our channels of advertising well and scientifically—that is, if we are going to get the best value out of the money we spend—then we must know something, at any rate, about the psychology of advertising. Not much can be said here on the subject, although a few points may be given, but the whole matter has been gone into exhaustively by an American professor, who has arrived at some very interesting conclusions. As may be supposed, the power of an object to force itself on the attention of a person depends very largely on the absence of other objects which might act as counter-attractions. The professor, after elaborate experiments, found that the result of doubling the number of figures in a paper exposed to view for a moment or two was to reduce by 50 per cent. the chances of any single figure being particularly noticed. By increasing the figures on the paper threefold, the chances of any one figure being seen was reduced to 33⅓ per cent. The application to advertising of the knowledge thus gained by experiment needs no emphasis here. It is obvious, and will save the publicity manager from many a pitfall.

Attracting Attention. It was also found that the power of an object to attract attention depended upon the intensity of the sensation aroused. Hence the value of good display. Contrast also largely assists in attracting and holding attention, and this applies not only to an announcement set in bolder and heavier type than the other advertisements round it, but also to one set in lighter type than the heavy displays all round. It is therefore often better to go one lighter than one's competitors rather than to attempt to annihilate contiguous advertisements by weight and massiveness and excess of colour. Repetition, too, has been proved a most valuable principle in fixing an object, a name, or an idea upon the mind. Hence the need for continuous advertising. Spasmodic effort never secures the valuable assistance that the principle of repetition does.

Other Principles Involved. Other principles that have by experiment as well as by practical experience been proved of the utmost value in securing attention may be briefly referred to. The value of an appeal to the feelings is great; hence the suggestion of the bright and the pleasant, in both illustration and matter, should always be attempted. Suggestion plays a large part in human life, and it is of the utmost usefulness to the advertiser. But the keen advertiser will not be satisfied with mere suggestion; he will remember that the great bulk of human-kind dislike thinking for themselves, and prefer to be told what to do rather than to make up their own minds as to what they should do. The direct command, therefore, "Get a jar today," "Tell your grocer you must have Blank's," "Write for a box at once," and so on, will often clinch the matter, when a mere general request or a suggestion would result in no business at all.

Advertising Appropriation. Advertising is too serious and too important an item of expenditure to be done in a haphazard fashion. The advertiser should always have some definite idea as to what he intends to spend during the ensuing twelve months. The sum set apart is known as the advertising appropriation, and some firms decide on the amount of their appropriation not only for the twelve months but for the two or three years immediately ensuing. This enables the publicity campaign to be properly organised and planned out, and the relation of one year's scheme to be intimately connected with another's. The actual amount set aside is, of course, a matter for each firm to decide for itself, but a word or two may here be said as to considerations that must be taken into account.

The advertising should be reckoned as a part of the selling cost, and should therefore be roughly estimated as a percentage on the amount of probable sales. But if the turnover has gone down, another consideration comes into account: Should the amount spent in advertising be more or less in the succeeding year? Some firms have been in the habit of making it less, on the principle of cutting down expenses; others have increased it after a bad year, on the principle that more advertising is needed to bring in more business. The latter is the plan that is now most favoured by up-to-date experts in business.

In reckoning the cost of advertising, however, we must have some idea as to what is to be charged up to this account. Here, again, there is a great difference of practice in firms. Some put down everything that can by any stretch of the imagination be remotely regarded as advertising the firm or its goods, as, for example, stationery. Not only do they charge up the printing on the notepaper and envelopes, but also the paper itself. Even invoice and statement forms and labels are, by some, regarded as legitimate advertising expenditure; and there are firms that place the expenses of travellers—salaries, commission, fares, hotel expenses, and samples for carrying—to the advertising account. If any distinction is made between the advertising and the sales departments, then obviously these should go down to selling and not to advertising. It would be almost as reasonable for a grocer to regard the assistant behind the counter as an advertising charge as for the manufacturer to do the same in regard to a traveller.

The scientific method, coming more and more into vogue, is to charge to the advertising department only such schemes and plans as are for publicity independent of the actual selling of goods. Thus in a scheme by which tradesmen were induced to stock largely a particular soap, by giving them an extra discount of 1¼ per cent., the amount of discount involved would go down as a selling charge pure and simple; but if with it was connected up a plan for getting window displays by

giving them a pound's worth of goods for the display, the latter would be charged to the advertising department. The sales and advertising departments, however, are so interdependent, and have necessarily to work in such close touch with one another, that it is not always easy to decide to which the cost of any particular scheme is to be debited. The matter must be decided carefully by every firm for itself.

Planning the Campaign. It is in planning out just what form an advertising campaign is to take that the most important part of the work comes in. Shall the publicity be obtained entirely through the newspapers? And if so, shall dailies or weeklies or both be used? Shall the great national papers, published in London, alone be used, or shall the provincial journals also be brought into service. And if so, are these to be the mornings or the evenings of the big towns and cities, or the local weeklies of the smaller towns and districts? Or shall posters on the hoardings be selected for the campaign, or enamel plates at the railway stations, or a house-to-house distribution of samples and literature? Or shall there be a combination of some or all of these methods, with others not enumerated?

Then again, shall the campaign be a general one, reaching all over the country, or shall it be confined to the big centres where the people congregate—London, Liverpool, Birmingham, Newcastle, and so on? Or shall a certain area be selected, town and country, as for instance, the Eastern Counties or the Midlands, or Yorkshire and Lancashire?

These questions must all be thoroughly thrashed out before any money is spent; and unless expert knowledge is available in the firm itself, it is always wise to consult specialists for advice, such as the big advertising agencies. It is certainly wise, however, for every large firm to have an experienced advertising manager and control its own policy in detail, while using the agencies as space-brokers and designers.

Choosing the Media. The media must be very carefully chosen. No one would, of course, be so foolish as to advertise a whisky in a Nonconformist religious weekly, nor malted milk in a racing journal. The most general and extensive advertising of ladies' blouses would hardly embrace the ironmongery papers or the "Journal of Chemical Science." But while such incongruous instances of useless advertising would not be perpetrated by the most ignorant advertiser, yet there are many cases scarcely less incongruous to be found every week, though they do not always appear so ridiculous to the lay mind.

Every class in the community has its special organs or its favourite journals; and when a prospective advertiser has decided to whom he means to appeal, expert advice is needed as to the channels through which these people are most effectually to be reached. It is expert knowledge, therefore, that is essential to decide upon the relative values of newspapers, magazines, circular letters, railway plates, hoardings, etc., for any particular purpose. Only with such knowledge can a wastage of money be avoided.

Specialist Treatment Needed. Every coat, of course, has to be cut according to the cloth; and whereas for a big campaign a combination of, say, newspaper advertising, billposting, sampling, and other methods may be used to give the maximum of results, in a smaller scheme it may be better to concentrate on one particular channel, as, for example, the newspaper. In any case, the trade must be notified as to what you are doing, either through the usual trade organs or direct by post and through your travellers. Propositions vary so, and different kinds of goods need such different kinds of treatment, that it is impossible here to give any stock plan of campaign. The advertiser must, first of all, think out clearly in his own mind what he actually wants to do, and then decide upon the best way of doing it, after weighing the pros and cons of a variety of means. So many advertisers make a bad beginning by never having any really clear idea in their own minds of what they want to do.

Various Publications. Of the newspaper as an advertising medium something is said below. Newspapers take a large and ever-increasing part in the work of publicity, but they are not alone among publications. The monthly magazine is also a valuable medium, and it has this advantage over the newspaper—that its life is not so ephemeral; it lies about for a month at least, and its advertisements have currency, therefore, during that time. Here, of course, as in all other forms of advertising, the right organs must be selected for the particular class of people it is wished to reach. Thus for first-class children's boots, a high-class jam, and so on, a publication like "My Magazine" would be selected, as circulating among exactly the class of people who would be likely to buy a high-class article or commodity.

Quality and Quantity of Circulation. Circulation is, of course, a very important matter to be considered. All other things being equal, it is much more valuable to insert an advertisement in a paper with a circulation of one million than in one whose circulation is only half that number. And in arriving at a decision, when comparing alternate media, it is important to know whether circulation figures presented stand for copies printed, copies sent out, or copies actually sold, exclusive of all returns, free copies, vouchers, etc. But even when all this is decided, quantity of circulation is not everything. Quality must be taken into consideration also, and to many advertisers quality is more important than quantity. For the advertising of a cheap margarine by a multiple-shop concern, a publication that had an enormous circulation—say, a million—among the poorer working classes would be valuable. But it would be worth nothing as compared with, say, "My Magazine" referred to above, if the article advertised was a high-class garment at a good price, although the circulation of the one would naturally be less than that of the other.

Classes of Journals. But the general newspapers and magazines appealing to all classes and conditions of people do not exhaust the valuable media open to advertisers. There are what are known as the class journals, those that appeal to certain sections of the community, such as religious papers, the women's journals, Nature and outdoor publications, literary journals, etc. All these are extremely valuable for certain purposes, and should never be ignored. We may put it stronger, and say that, wherever possible, sections of them should be included. For many articles it is by means of the class journals that the advertiser can most effectively and most economically reach his public.

Large Spaces versus Small. The size of the spaces to be taken in the newspapers and magazines depends largely upon the amount of

money that can be spent over a given period. It also depends upon what exactly the advertiser is desirous of doing. If, for instance, he has about £250 or £300 to spend, and ten thousand ladies' umbrellas to sell, it might be well to take the front page of a big London paper, or perhaps even two pages, thereby spending all the money at once. By such an effort it would be quite possible and probable to clear the whole stock of articles, and achieve the purpose desired.

On the other hand, if the advertiser's aim is to keep a steady and increasing trade going, with some article of general use as a household commodity, then he does not want to make one big effort like a flash in the pan, with nothing succeeding it. In such a case he would take smaller spaces, letting his announcements appear perhaps once or twice a week, and occupy eighths or sixteenths of the pages. Even smaller spaces, such as two or three inches, are extremely valuable if run as series, provided the article advertised is some well-known popular commodity that needs little or no description, such as Chivers' Jellies, Mellin's Food, etc. In this case the idea is general publicity, by keeping the name constantly before the public, so that they shall not forget it, and so that a rival article shall have less chance of supplanting it in the public mind.

Advertisements should, as far as possible, appear next to matter, even if a higher rate has to be paid. Right-hand pages are better than left, and the tops of pages or columns are better than other parts, unless in the lower place a solus position is secured —that is, a space entirely surrounded by matter, or having reading matter at the top and on either side, or on one side if the advertisement is in an outside column. Such positions on right-hand pages are the most valuable of all. The reason right-hand pages and columns are better than left is that the eye naturally falls to the right rather than to the left, owing to the fact that we are right-handed and right-brained.

A small and striking advertisement appearing again and again is in most cases better than a large announcement published occasionally, on a principle that "a constant dropping wears away stone," and a constant hammering eventually does its work. The cumulative effect of regular and constant advertising cannot be over-estimated. As far as possible a regular advertisement should occupy the same space and position in different issues, in order to assist this cumulative effect.

Type, Border, and Pictures. It is in the selection of type, borders, and pictures that the expert has his opportunity. Many striking and artistic types are now available in the printing establishment of every high-class paper and magazine. Excellent borders, too, may be had for the asking, and the advertising man who knows his business will soon be able to know what types and borders are best suited to his purpose. It is a mistake to change too often the particular kind of type used for a firm's name, or the title of a branded article, as in doing so the continuity is broken. Some of the most successful advertising of recent years is that which has retained a particular type or border with very slight modifications. Whatever change is made there should always be something similar about a new advertisement to that which it displaces, in order that the continuity may be preserved.

Illustration plays a large and growing part in effective advertising. The picture should always be simple, without an excess of detail to distract the eye; it should be well drawn, and it should tell the story. The irrelevant picture is of little or no value; in fact, it often leaves an impression on the mind that prevents the right impression from remaining.

Mr. Herbert N. Casson describes advertisements with such pictures as "April Fool Advertisements." "The distinguishing mark of this species," he says, "is a headline or illustration that has no connection with the subject. Its aim is to trick people into taking notice of it. Apparently there is nothing in the goods to interest the public, so the advertiser throws in a picture of the Eiffel Tower, or an ostrich—anything that happens to be handy—to brighten up his advertisement. The result is an advertisement that may be very catchy and attractive, but that is almost quite worthless as a seller of goods. It does not create a strong impression. It does not convince. It divides the reader's mind, and the part that is interesting is not the part that is of any value. Worse still, it gives a shock to the mind. It shows you a fine picture of the Eiffel Tower, and then, when your attention is secured, it says 'April fool! I only want to tell you about the Smith brand of shoelaces.'"

Badly drawn pictures cheapen an advertisement —together with the article advertised. They should never be used. Of course, in small spaces there is often not room for a picture, but wherever possible a really relevant picture does help in arresting the attention in the first place, and leaving an impression on the mind after the paper containing the announcement is laid aside. Care must be taken to supply a newspaper or other journal with such blocks as it can print well. Half-tone blocks with a fine screen are useless for newspapers printed on a rough, inferior paper. In all cases of doubt it is much better to be on the safe side, and supply good line-blocks.

Black versus White. Then comes in the question of the relative value of black on white and white on black. Many advertisers think that they can secure more than a fair share of the attention of readers by making their announcements heavy, with a predominance of black. This is usually done by having a panel of black with the announcement upon it in white lettering. The effect is dazzling; it is far from pleasing, and it is doubtful if, all things considered, it really has any more lasting impression on the mind of the reader than black on white. Certainly the effect in the pages of the newspaper is so ugly that all the leading newspapers are now declining to receive or print such blocks.

Copy. Of course, when speaking of the importance of selecting good pictures, types, borders, etc., it is assumed that the copy or matter is effective. It is the most foolish economy to buy expensive space in newspapers and magazines, and then to fill it with anything but the very best of matter. Copy must be written by one who is an expert in the business, whether it be long or short. And here arises the question as to whether short, snappy advertisements, with a few lines that can be taken in at a glance, or reasoned arguments, running to four or five hundred words and more, are most effectual in attracting business. Both styles have their advocates, and for both there is much to be said.

The truth probably is that both styles are good. For some articles and commodities the short copy is, in a general way, best, while for others the long copy pulls most. Patent medicines are an instance in which long copy seems to be extremely successful. People will read an almost unlimited amount

of matter consisting of testimonials and descriptions of cures effected, or said to be effected, by pills, ointments, embrocations, and so on. On the other hand, for household commodities like jams, jellies, cocoas, etc., a few lines would seem to be more useful. But in neither case can any hard and fast lines be laid down. It is good from time to time to tell the story of the jam or jelly or cocoa at extended length; and where the story of the ointment or whatever it may be is being told at length fairly frequently, it is very useful to give reminders of the name between the appearance of the larger advertisements.

Style Needed. Whether the copy be long or short, it must have style and individuality. If it be short, then the sentences which give in a few words the points about the article must be pithy, slightly epigrammatic, though not so brilliantly clever as to be over the head of the ordinary crowd; and the language must be simple enough to be plain to the dullest understanding in a moment. People will not in these days stop to think over advertisements of this type, and so the phraseology must be very plain, and the words Saxon as far as possible. Thus, "begin" is better than "commence," "end" than "conclude," "see" than "observe," and so on. There should also be a rhythm in these sentences, harsh combinations of words being avoided. In this way the memory of the reader is assisted to retain what he sees.

As to the larger copy, as much care should be exercised in preparing this as in the production of an article. The language should be good, nervous English, but above all it should be absolutely clear. The reader should never have to read a sentence twice, or even to dwell on it, in order to grip its meaning. Long sentences should be shunned, but, on the other hand, the sentences should not all be so short and snappy as to give a fragmentary, broken, and disconnected feeling when being read.

If the story of a product or its use or composition or history is being told, then the story should be consecutive. Point should lead up to point, so that, after reading the advertisement through, a person shall have in his mind a clear idea of the matter by means of which he is unconsciously compelled to conjure up a mental picture. It is the mental picture that will live in the memory and recur. Thus, if the story of a food product is being told, the reader should find rising in his mind a scene in which fresh air, hygienic surroundings, a perfectly clean factory, and healthy, rosy workers, with spotlessly white overalls, all combine to form a pleasing picture. This picture will then recur whenever the commodity in question is mentioned or appears to the eye.

The Expert Advertising Man. Obviously, literary skill is required for this, hence the need for experts as copy-writers. Mere commercial knowledge is not sufficient for an advertising man; he has to have such knowledge, but in addition he must be something of a salesman, an artist, an editor, and an author. Mere tricks of composition, such as alliteration and elaborate metaphors, should in a general way be avoided, but, as already mentioned, there must be rhythm and what has been described as "the music of syllables." Exaggeration, a redundancy of adjectives, superlatives, attacks on rivals, should all be avoided. They belittle the advertiser and shake confidence in his bona fides.

It has been said that a good advertisement is as rare as a good editorial or a good novel. "If Edwin Markham worked fifteen years to write 'The Man With the Hoe,' it is not to be expected that a famous 'ad.' can be written in fifteen minutes," says an expert. This is true; and although the public who read and remember good advertisements never dream that any particular pains or time have been expended in their preparation, it is safe to say that all advertisements worthy of the description "good" have in their composition a vast amount of "sweat and blood." The famous advertising phrases, "Worth a guinea a box," "I hear they want more," "Made in the country, away from the dirt and the dust of the town," are not, as a rule, brilliant inspirations, but well-beaten-out gold, modelled and remodelled many times before they reached their present form.

Topical Advertisements. There is a great advantage to be gained by giving a topical touch to advertisements. Very often a person who would never trouble to read an ordinary advertisement will be arrested by some topical allusion, and will be induced to read on until he has assimilated the strong meat of the announcement to which the topical reference was but the relish. Many excellent instances of topical advertising have appeared in the newspapers and magazines during the Great War. Some old-fashioned firms are too dignified to descend, as they describe it, to topicality, but, as has been pointed out before, dignity has ruined more men than drink. Of course, it goes without saying that anything in the nature of vulgarity must be strictly avoided.

Definiteness Needed. There is one thing that cannot be over-emphasised: an advertisement should always be definite and specific. There is something wrong about the wording of an announcement for shirts that could be transplanted bodily to an advertisement for gold-clubs, or a gramophone advertisement that would equally well fit an Axminster carpet. Then about every article or commodity that is being well patronised by the public there must be some one selling point at least which leads people to buy it in preference to similar goods turned out by other manufacturers. What is that one point? Or if there are two, what are they? It is the advertising man's business to find these out, and clearly and concisely to state them in his announcements.

Hard Work Essential. Advertising is by no means an easy business. It is one of the most difficult of professions. As Mr. Herbert N. Casson has said: "The publicity man has a bigger job than the salesman. Why? Because the salesman handles men one at a time, while the publicity man handles the whole public at once. The man who writes the 'ad.' can't make a joke on the other fellow, because the other fellow may read it. He can't whisper of special favours. He has to work out in the open, where everybody can see him. If he makes a mistake, he can't forget it, like a salesman; or blame it on induction, like an electrical engineer; or deny it, like a public official; or bury it, like a doctor; or charge twice for it, like a plumber. He has to face it, and own up. The publicity man stands between his company and the public. He must understand both. He must interpret each to the other. If he does not know his company, he has nothing to say; or if he does not know the public, he does not know how to say it. A real, thoroughbred publicity man knows the public as the pilot knows the sea. He knows the rocks and the currents and deep places. He makes it his

business to keep in touch with all sorts of people. . . . The real publicity man works over his 'ads' as an architect works over his designs."

The Test of Distinctiveness. Many an advertiser, looking at his announcement appearing regularly in the papers, thinks that it stands out from all the other advertisements. And to him it undoubtedly does. Even if he is glancing through a paper with no thought of his advertisement in his mind, his eye instinctively goes to the announcement as he turns to the page on which it is. But this is no real test of distinctiveness. The man can pick out his own house in a street containing a hundred villas, all alike. To him the house is unique, but to strangers it is just one of a hundred. And so it is with an advertisement. If a man wants to know whether it is really distinctive and stands out so as to attract notice, he should take the opinion of other people.

If an advertisement is to be in two or more colours, as when it appears on the cover of a magazine, it is worth while to remember that red is the colour that stands out best. Green is also a very distinctive colour.

Getting the Help of the Salesmen. It is always wise for the advertising manager to keep in close touch with the salesmen. They can give him many hints and points that perhaps he himself has no knowledge of. They know all the possible arguments against the goods they sell, for they are hearing them every week from the shopkeeper, and some of these are sometimes worth meeting beforehand indirectly in the advertisements that are appearing regularly in the papers. On the other hand, the advertising manager must exercise his discretion. If he is going to carry out every suggestion received from his firm's salesmen, he will spend a great deal of money and make a rare hotch-potch of the advertising. The wheat must be sifted carefully from the chaff; and although the chaff may predominate, there is always a certain proportion of wheat well worth having.

Trade Paper Advertising. So far, general advertising has been dealt with, but in most businesses, particularly manufacturing, a certain amount of advertising in the trade organs has to be done regularly. The character of this is, of course, quite different from the advertising to the public. In the latter the idea is to give reasons why an article or product should be used, but in the trade paper we have to tell why the shopkeeper should stock our goods. Here such phrases might be used as "Good profits, quick returns," "The beverage that is advertised all the year round," "A large margin of profit," and so on. Blocks of the article or the package may very well be used.

The articles which follow describe principally various phases of newspaper advertising, all of which are of great importance, and must be thoroughly understood by the advertising man.

CHARLES RAY

ADVERTISING AGENCIES

BY WAREHAM SMITH

Advertising is obtained either through an advertising agency or direct from the advertiser, and the agents handle about 90 per cent. of the business appearing in newspapers.

It will be seen from this that the advertising agencies play a very important part in the business, and their position in the field is rather a peculiar one, for the reason that although they work ostensibly in the interests of the advertiser, they receive their remuneration from the newspaper. On all contracts placed by the agency the newspaper pays a commission, varying from 10 per cent. to 15 per cent., according to the standing of the publication and its power to command business. Various other arrangements are often entered into, such as an additional discount for cash, or an extra commission if the business received exceeds a certain amount. The agency is responsible to the newspaper for payment for contracts placed by it, and is regarded as a principal, all contracts being made as such, and not as an agent of the advertiser.

How the Agent Works. It is not, perhaps, of great importance for present purposes to inquire into the inner working of an advertising agency, but it is at least relevant to the subject, and digression in this direction may not be uninteresting. The agency acts: (1) as space-broker—that is, buyer of space from the newspaper on behalf of the advertiser; (2) as advertisement manager and adviser to the advertiser.

In either case the commission paid by the newspaper is the same. Some agency businesses consist entirely of the former class of work, some the latter. Others combine the two according to the requirements of individual clients. Generally one of two methods is adopted by the advertiser in prosecuting his campaign:

(1) He organises an advertisement department under the control of a man who combines a knowledge of advertising with the study of the exigencies of the advertiser's particular line of business, or (2) he places himself almost (in some cases *quite*) unreservedly in the hands of an agency. In the former case he makes such arrangements as will, in his opinion, ensure that his business will be properly and profitably conducted.

His advertisement manager is generally a man with an extensive knowledge of the art of advertising. He has learnt from experience what to buy in the way of space, and the lowest rates at which it may be obtained. He designs copy, or has in his department experienced copy-writers, and, being on the spot, he has his fingers on the pulse of the business, and should be able to tell without loss of time when a publication or a particular advertisement fails to show a profit on the outlay. Almost invariably he employs an agency to act as space-broker, to make the necessary arrangements with the newspaper. By doing this he often saves time and money, the agency, acting for several advertisers, being frequently able to buy more cheaply.

Importance of Agency Work. Turning to the second method, the properly equipped agency can—and generally does—render very important service to the advertiser, whether his outlay be large or small. It may act as an advertisement manager, and, in addition, bring to bear the experience gained by years of experimenting and observation made in the interests of numerous clients with diverse interests. The agency maps out the campaign, the publications to be used, advises as to buying space, and secures best positions possible. It writes the advertisement copy and booklets; executes illustrations, and makes the process blocks; designs posters and sees that they are properly displayed; organises, where necessary, a follow-up system; originates selling schemes; checks accounts, to make sure that the advertiser has received the space ordered and charged for.

THE NEWSPAPER AS AN ADVERTISING MEDIUM

By J. Murray Allison

Every advertising medium has its uses and value. For many purposes the daily paper is supreme. In its highest developments, advertising is itself news—news about merchandise, news about the business affairs of the world, news about novel or advantageous commodities of daily life. Such daily-life news is best appreciated when published in a paper which appears daily to print the news. It is also in the daily paper, cheek by jowl with public news, that the announcements of the business man—Government loans, municipal issues, the prospectuses of public companies, and the like—find their proper atmosphere. There are, moreover, certain advertisements for which the daily paper is the only possible, the only natural medium; such are advertisements for servants, announcements of the theatres, concerts, public gatherings, meetings, and, of course, Births, Deaths, and Marriages. These partake more intimately than the other advertisements of the nature of news. Each is an announcement which states a definite, tangible fact, for which the daily paper is the one suitable channel of communication.

Requirements of *daily* life—I mean commodities of household consumption, the needs and luxuries of every household every day—need the daily paper as the bearer of their message to the public. There are needs of less frequent fulfilment which may be advertised in more leisurely publications, the weeklies and monthlies, though the daily paper is unsuitable for hardly any.

The Serious Side of Advertising. For the advertising of serious books and reviews, the daily newspaper is a highly eligible medium, because of the frame of mind in which it is read. The daily paper is itself serious in spirit. It goes with the business man to his office; it is brought back to carry the news of the day to his household. It discusses weighty matters with appropriate gravity. The mind of the same reader is much better attuned to serious advertising when the daily paper is before him than when he reads for amusement the lighter weeklies and magazines. The same reasons which make the daily paper a superb medium for advertisements of important books make it applicable to the advertising of expensive and deliberate purchases. An estate or a house, or anything else that is bought to last a lifetime or for a long period of years, will not be sold by light arguments, or bought in a frivolous frame of mind. Chattels of price—a grand piano, a suite of furniture, a motor-car or equipage, or a cellar of wine are examples—will be best advertised when the reader is seriously disposed: still more an investment will be made then, and not in hours of relaxation.

The daily paper, however, is not closed to advertisers of luxuries and amusements. More especially those which a man buys as presents for his family, or upon which (by reason of their high expense) he is generally consulted, can with enormous advantage be advertised in the daily Press

Economy in the Dailies. The advantages of the daily newspaper do not end, however, with its unique applicability to certain current advertising. The daily paper has a special appeal to the advertiser on the score of price too. It can sell its space at a much cheaper rate per inch per thousand than any other medium, except the great news-weeklies which resemble it in character and outward appearance. One factor of this circumstance is that the news-journal can be printed upon paper very much less costly than that upon which the illustrated weeklies and magazines are published. Another is that the large circulations of papers that are strictly newspapers make them cheaper to print, by spreading the initial cost of editing, news, and typesetting over a large number of single copies. Large circulations also make possible the use of fast, and therefore economical, printing-presses.

Admitting, then, that the newspaper Press offers him special advantages, an advertiser has to determine the value for his own purposes of each individual publication. In order to arrive at an estimate of this value he will ask himself, in respect to each paper, certain questions, such as, What is its circulation? What is the status of its readers? What is their capacity as buyers? Here we reach a very interesting and delicate situation.

The whole relation of circulation to the price for advertisements is an interesting and complicated question for advertisers. Some papers wisely state their circulation, others wisely do not. One class relies on the number, and the other on the quality, of their readers.

Sunday and Provincial Papers. The relation to advertising of the great Sunday weeklies is in many respects identical with that of daily papers. The extension of daily paper circulations has seriously affected the former greatness of the provincial weeklies. Very few families in the kingdom get through life today without a daily paper, and the dailies of large cities like London, Liverpool, Manchester, Leeds, Glasgow, etc., cover vast areas of population formerly reached only by the provincial weekly newspapers. Thus the influence and advertising value of the latter have greatly declined. Many of them are still powerful, and practically all respectable. Their decline from a former paramount position in rural Britain has led to consolidation, the same paper being published in a number of towns, with localised title-headings, a small amount of matter of purely local interest being peculiar to each edition.

Censorship of Advertising. How can the newspaper help the advertiser? One way in which a paper can help the advertiser very materially is by safeguarding the environment of his announcements, keeping its own advertising columns as clean and as reputable as its editorial columns. The policy of the "Times," and, of course, of other high-class journals, is to refuse any advertising which is contrary to good taste, untrustworthy, or fraudulent in intent. The presence of questionable advertisements prejudices the whole of the advertising in a newspaper. Only by the assurance which experience brings that the advertising matter is unimpeachable will readers look with favour upon the business announcements which a paper publishes. An advertisement gains force and value from the prestige of its medium, and advertisers are not slow to appreciate the importance of this.

Control of Display. Another matter in which the paper can help the advertiser is, in my opinion, by limiting the kind of "display" in its advertising pages. I hold the opinion, and I believe it is a sound opinion, that the presence in a page of an unsightly drawing, often accompanied by type unduly large and black, damages every other advertisement and defeats its own object, since the only advantage of large and

black type, and of blatant illustrations, is contrast. Where the same "bad eminence" can be attained by all comers there is no pre-eminence. Advertisers whose "copy" is refused by newspapers on these grounds often at the moment feel aggrieved; but, upon reflection, they are able to see the wisdom of the advertisement manager who will not allow them to enter into a rivalry of this sort.

ADVERTISING FOR RETAILERS

By Richard Burbidge

There are two ways of advertising a retail shop, or —shall I say?—two divisions of retail-shop advertising. One is to utilise the Press; the other is to employ miscellaneous advertising by post—circulars and catalogues being forwarded to old customers and to addresses of those whose custom is sought. In the case of a shop doing a good and progressive business, Press advertising is the most important. By means of the newspapers the retailer can speak to millions of persons every day, and invite just the persons whom he wants to come to his shop. Naturally, much depends upon the advertisement.

As a general principle, it may be said that the right purpose of a retail advertisement in the Press is to bring customers to the shop to buy a specific article. It must be a good article, of course, giving full value for the customer's money. That particular article should prove that the shop is worth patronising in the future. A satisfied customer is a permanent customer.

Importance of Good Copy. It does not seem to be generally recognised that the success or failure of a retail establishment may actually depend upon the wording—commonly called the "copy"—of its advertisements. Advertising is a science which amply repays all the time devoted to its study. The retailer's advertisements should be bright, crisp, simple, and direct in language, and contain prices stated in plain and unmistakable figures. There are experts who declare that an advertisement should contain the announcement of a single article only—an article to bring customers to the shop, where they can see other bargains. That is a good principle, but it is not an infallible one. At sale-time, for example, shop advertisements are miniature catalogues, containing, perhaps, in a couple of columns of a daily paper anywhere from twenty to forty articles. The object at sale-time is to attract all classes with all kinds of goods; therefore the announcement of a single article would, in my opinion, be a mistake.

Of course, any retail advertisement is actually an advertisement of the business as a whole, but a big business is only built up by selling many articles. The first thing to do is to get your shop well known, and that means that the majority of your preliminary advertisements must deal with some specific article on which the retailer relies. He knows that it will attract hundreds or thousands of customers, and all he wants is to get them inside his shop. Therefore a good retail advertisement, although it may contain offers of numerous articles of merchandise, really is advertising the shop after all. That is what it is used for.

Put the prices in the advertisements. Many a good customer is frightened away because she fears that the article specified may be dearer than she thinks it is. No one is going to risk humiliation by suddenly discovering that the price is beyond the purse. As for illustrations, my experience is that a good illustration is always worth the money, and a poor one only so much hard-earned money thrown away. If a paper cannot reproduce blocks well, do not illustrate advertisements in it.

I would like to impress upon retailers the need for versatility in their advertisements. How often do we see the same advertisement appearing day after day, not a word altered or a phrase brightened! The reader's eyes wander mechanically over it without the brain receiving any impression; in fact, it is money wasted.

Advertising by Post. I now turn to the question of advertising by post, with circulars and catalogues. It will be found a good idea to regard this class of advertising as the foundation of your business, leaving Press announcements to build upon the foundation. In other words, the Press advertisement is like the mason's work on a building. Catalogues are apt to be thrown away after a general glance, or they may be merely laid aside and forgotten. The daily or weekly advertisement in the Press revives memories of the catalogue, and therefore each kind of advertisement dovetails with the other, forming a continuous whole.

The Press advertisement brings more inquiries than the catalogue and the circular, but every inquirer should be made a customer, not by newspaper announcements, but by a judicious supply of advertising literature. Send a catalogue or a circular to the right person at the right time, and follow it up by a prominent display in the Press, and the result is always satisfactory.

Catalogue Lists. Every well-organised and progressive shop keeps a carefully compiled list of customers, and notes as to the purchases of each. This list is an index to the character of the persons patronising the shop, and indicates the kind of goods they want. The wise retailer, therefore, keeps his list up to date, and sends catalogues suited to the requirements of each customer. A very important point to bear in mind in sending a catalogue is to enclose it in an envelope of decent quality. The catalogue that arrives in a flimsy envelope is more often than not consigned to the waste-paper basket unread, or even unopened. The more often a catalogue is issued, the better it is for the retailer.

Advertising during Sale-time. Advertising during sale-time is a difficult thing, but, speaking from experience, I should advise the selection of a dozen different bargains to be advertised, confining them to things in general use, such as bedding, dresses, linen for both sexes, and similar articles. Again I say, constantly change the advertisement.

Points Worth Noting. A few remarks of a general nature may be worth making, especially to the retailer in the smaller towns. First of all, do not advertise an article and put the customer off it when she enters the shop. Take one article at a time, and boom it. It must be a first-rate article, of course—one on which the vendor can stake his reputation. That article will serve as an introduction. It will get customers into his shop, and once they are there he need fear nothing.

A big clientèle having been secured by advertising, the retailer should be most careful not to lose it. He must go ahead, and keep going ahead all the time.

In conclusion, advertising is of vital importance to the retailer, and any time and trouble spent on it is always amply repaid. A shop must be kept in the minds as well as the eyes of the public. For the

thousands who can see it there are millions who cannot. To reach them, the Press must be used, but success depends upon the methods adopted.

MAIL-ORDER ADVERTISING

By J. McBain

Mail-order advertising is the publicity employed to sell goods by post, whether it takes the form of advertisements in the daily or periodical Press, circular letters, booklets, folders, or a combination of any or all of these elements. The seller, or advertiser, may be (1) a general mail-order trader catering for a variety of needs, and supplying such things as household linens, blankets, rugs, dress materials, suits, furniture, cutlery, and a thousand other articles either for the home or for personal adornment. Such a trader may have showrooms where local customers can make their purchases, but the bulk of his trade will be handled through the post; (2) a trader in a speciality; (3) a particular department in a retail business formed to supply the requirements of those who cannot conveniently shop over the firm's counters.

The aim of the "general" mail-order man is to secure as big a list of customers as possible, irrespective of any consideration for the profit he may make on the first transaction. Supplying, as he does, a multitudinous variety of articles, he need not, and probably does not, hope to make a profit on his first sale; that is to say, if the prime cost of the article, plus the cost of advertising it, exceeds the amount he receives from the customer, he has not necessarily any cause for dissatisfaction. This customer is now on his books, and, assuming that he has no reason to regret his purchase, will in due course, at small cost, be persuaded to buy other articles; or, if his first purchase be something consumable, such as a box of cigarettes or cigars, he will in all probability repeat the order.

It is obvious, therefore, that a mail-order advertiser of this type makes his profit out of a particular customer, not on the first sale, but on the sum total of the transactions he has with that customer.

To treat a customer generously is a good thing in any business, but perhaps in none is it more desirable and more profitable than in a general mail-order business. It assists in creating that goodwill which is so valuable an asset to the mail-order man, for it saves him, as we have just shown, from one-half to two-thirds of his cost of selling.

With the mail-order department of a large retail business the same general principles apply to the question of profit margin.

Advertising a Speciality. Very different is the position of the advertiser of a speciality, Either he has no other article to sell to a customer. or, if he has, the chances of subsequent sales are too remote to be worth taking into account. It is absolutely essential, therefore, that he should make a profit straight away. This means that the margin of profit must be very much greater than in the cases already discussed

Announcements in the daily or periodical Press represent the chief means employed by mail-order advertisers to sell their commodities. These announcements may attempt either to sell the article to the consumer at once, or they may only attempt to arouse the reader's interest to the point of inquiring for further particulars, which are duly sent to him in the form of booklets, leaflets, folders, circular letters, etc. In the case of more expensive articles, costing from, say, ten shillings upwards, it is usually hopeless to endeavour to effect an immediate sale. The British public thinks twice about remitting any considerable sum of money for an article until ample opportunity has been afforded for considering its merits.

Selling an Expensive Article. A mail-order advertiser, therefore, if desiring to sell a comparatively expensive article, should advertise in the first instance for inquiries, unless he is prepared to offer his goods on approval or guarantee return of money in case of dissatisfaction.

But whether immediate sale or inquiry is the object of the announcement, the form of the advertisement is more or less the same in each case. It used to be an old saying that in an advertisement the less said the better. This is certainly not true of mail-order advertising, in which the rule seems to be rather that one should endeavour to get into the available space all that one can possibly say about the goods and the offer without making the advertisement unattractive and unreadable.

It is a well-known fact that successful mail-order advertisers study with the minutest care all data bearing upon the pulling power of their advertisements, and the discovery of some little point which has hitherto escaped their observation has often led to largely increased results.

While it is impossible to draw up hard and fast rules, it can at least be said that simplicity should be the keynote of all mail-order copy. All attempts at cleverness should be severely repressed, and the advertisement which is content to be a simple, straightforward statement will in nine cases out of ten bring most business.

With regard to the particular media which should be employed by mail-order advertisers, the best results appear to be obtained from London morning papers which enjoy a national as well as a metropolitan circulation. After these come the more important weekly and monthly publications, and after these again the provincial Press. Media whose circulation is confined exclusively to large towns where facilities for purchase over the counter are abundant should be avoided.

Up to this point our remarks have applied equally to advertisements seeking immediate sales and to advertisements seeking inquiries. With regard to the former there is nothing more to be said. With regard to the latter we have to convert inquiries into sales.

Inquiries not Sales. This is a suitable point at which to state with some degree of emphasis that inquiries are not sales. An advertisement may produce one thousand inquiries and yet show a loss, while another advertisement producing only five hundred inquiries may show a handsome profit. The element which determines the value of the advertisement is the ratio of sales to inquiries.

A Typical "Follow-up Scheme." Assuming that the office organisation is all that it should be, what are the conditions with which we have to deal? An advertisement has appeared inviting those who read it to apply for further particulars of a certain article. There has been considerable response, and the office has in its possession the names of a number of people who have taken the trouble to inquire either by using a coupon or by writing a postcard or letter. The advertisement has cost, let us say, £20, and the problem now is to convert into sales a sufficient percentage of these inquiries to recoup the cost of the advertisement, and show, in addition, as large a profit as possible.

It is obvious that if the article has a big margin of profit it will be possible to make more than one

attempt to bring each inquirer's interest to the buying point. A typical "follow-up" scheme, as practised by a mail-order house dealing in specialities, might be as follows: (1) The answer to the inquiry, consisting of a folder or booklet, describing the article and the terms on which it is offered, and a letter stating any salient points in the offer;

(2) A reminder, consisting of a brief letter or even postcard, directing the recipient's attention to the previous communication;

(3) An offer of the article on approval, consisting of a letter explaining the offer, a leaflet or folder recapitulating the matter contained in the original booklet, and a reply postcard, to be used if the recipient wishes to avail himself of the offer.

(4) Another reminder, directing attention to the offer on approval.

With regard to No. 1, the chief item is, of course, the folder or booklet; and a wise advertiser will devote considerable time and thought to its preparation. It should be long enough to enable the advertiser to tell his story fully and clearly, but not so long as to risk wearying the reader.

Good Paper and Print. Speaking generally, it will pay to spend enough to ensure good paper, printing, and get-up. The use of two colours is almost indispensable in a piece of advertising matter which is to stand out of the ruck.

The covering letter should be made as strong as possible. Not a single unnecessary word should be employed. If possible, the letter should be written in the first person, and signed by an individual, thus creating in the mind of the recipient the desirable impression that he is dealing with a definite person and not with shadowy and soulless office machinery. The "second shot" will consist of a letter.

Shot No. 3 marks a new departure. Two previous communications having proved fruitless, it is assumed that the inquirer has lost the greater part of his pristine interest, and that some entirely new proposal is necessary in order to arouse him from his lethargy. What more suitable than an offer to send him the article on approval, carriage paid both ways? Such an offer not only argues confidence in the merits of the article, but a desire to deal frankly with the customer.

The Offer "on Approval." The offer on approval is the great stand-by of many mail-order advertisers, who rely on it to produce much business they would not otherwise get. Of those who take advantage of the offer, 60 per cent. to 80 per cent may reasonably be expected to become actual buyers, always provided that the article is found to be as described. In any event, some new proposal or offer is needed in this third shot.

Shot No. 4, which completes the series of "follow-ups," requires no special comment, except that, being the advertiser's swan-song, the appeal should be as strong as possible. In the case of most propositions it will not be found profitable to make further efforts. Indeed, where the margin of profit is small, Nos. 2 and 4 would have to be dispensed with, and No. 3 made to mark the limit of the advertiser's follow-up system. As to the intervals of time that should elapse between the shots, an average period of ten days is most suitable.

The question of postage is a much-debated one in connection with "follow-up" systems, some favouring penny and others halfpenny postage. From inquiries made by the writers, the general consensus of opinion appears to be that penny postage will bring more results, but that the difference may not compensate for the increased cost.

WINNING CONFIDENCE

By Sir Thomas Dewar

The successful man of today must treat his public honestly as from man to man; in absolutely no other way can he make them his clients. True, public support can sometimes be won by a successful advertising coup, but the buying public are not sentimental; they quickly find out if they are not getting their money's worth; and once a trader loses their confidence, practically nothing can win it back. When a man has anything beyond brains to sell, he soon finds out that morality and money-making have to keep pretty closely hand in hand. No matter how much is spent on an article that is not good value, it will never pay. If you succeed in deceiving the public and they resent it, you will find they have long memories. It is a good deal more expensive to reclaim a lost name than to make a new one.

Beware of Change. To keep the confidence of the public you must not make abrupt changes; the public of every country are very suspicious. I have had good proof of this. For example, some years ago in the Malay States circumstances made it necessary for us to change the whole style of the labels on our bottles. Instantly there was a sharp decrease in the orders, and the amount of the shipments fell considerably. I found on investigation that the fall was solely due to the change in the labels. The well-off Chinamen, who were the chief consumers, although they could not read a word of English, knew the label well, and would not be convinced that the contents of the bottle were the same if the label were different. It took many years to regain their confidence; in fact, we did not succeed until they had become accustomed to the label.

It is a most dangerous test of public confidence in any way to alter a label or trade mark to which they have become accustomed. Even if you have gained two or three extra medals at exhibitions, to add them on to your label or trade mark will raise suspicion. This is a curious but undoubted fact.

To copy another man's form of advertising is never successful, and to copy the methods of a man in your own business is simply to advertise your rival's goods. The public always associate certain methods of advertising with certain names.

Map out a policy for yourself, be sure you are right, and then go right ahead.

To keep the confidence of the public one must keep persistently before them. "The man who on his trade relies, must either bust or advertise" is sober fact for trading men. It is no use to offer a reward for the return of a lost opportunity. Advertise persistently, right from the beginning. Keep at it. Remember that a prophet is no prophet in his own country unless he is an advertising man.

Slow Returns. To get the full benefit of public confidence from advertising, you should not expect any outward return until the end of the third year; but if you don't get any by the end of the fourth you may take it that your money is lost. You are making some mistake, or your article is not all right. There are two certain ways of losing money: first, to advertise and then leave off; second, to advertise a bad article. Unless you can show an increasing turnover in your business you are not holding the public confidence. Something is wrong. Investigate.

Training. Office Work. Estimating from Bills and Drawings. Measuring Up. Extras. Day Work.

IN BUSINESS AS A BUILDER

THE building trade is one of the most important and permanent industries of the country, and is likely to attract into its ranks in the future, as it has done in the past, young men of energy and enterprise. It may be well, therefore, before our subject-matter proper is dealt with, to call the reader's attention to the great changes that have taken place in this trade during the last thirty years, and have most vitally affected it and the prospects of those who intend to enter this business.

Changes in the Building Trade. There is no doubt that for the moment, though it is to be hoped not permanently, the old-fashioned type of builder is on the decrease; the builder who had first-hand practical knowledge of some or all of the trades employed in the erection of buildings, who had gone through a most practical training in the workshops, and who, in proportion to the thoroughness of his training, took pride and interest in his business—this type of builder is being pushed to the wall in the stress of modern competition. His success depended not merely on his ability to undercut his competitors in a tender list of twenty but on a reputation gained for sound, though not always, it must be confessed, cheap building; and it is open to grave doubt whether the building public in the end stands to gain by the gradual disappearance of this type. Into his place is stepping the mere financier, who chooses the building trade as the field of his operations, and whose training has made him a master of office detail, but has left him without any practical knowledge of the various trades connected with his business. Besides the change in the type of builder, there is another tendency to be noted, which is, perhaps, its necessary concomitant—that is, the tendency on the part of furnishing firms and great stores to establish an architectural and building branch of their business, and with the help of the large capital they have at their command, to enter into competition with the genuine contractor; for in these days of rush and hurry it is apparently a tempting consideration to be able to choose your house at the same place as you buy your furniture. It should be noted, however, that the competition of these firms has at present more effect on the decorative side of a builder's business than on the actual contracting, though not without its influence here, too.

Signs of the Times. These changes are undoubtedly signs of the times, and must be taken into consideration by any one proposing to enter business as a builder; but, significant as they are, there are reasons for hoping that they indicate a mere temporary phase, and not a permanent alteration of the conditions under which the building trade has been carried on in this country. Architects, too, it is to be hoped, will be found on the builders' side in this matter; their work is far more likely to be intelligently and efficiently carried out by firms whose interests lie only in the building trade, and whose principals have practical knowledge of building detail, for they will thus secure the great advantage of dealing direct with such builders instead of with the subordinates of great financial houses, as they would have to do if the "trust" methods of business were to prevail in the building trade.

Technical Training. Technical training may be said to be the foundation stone of success for the builder and of most vital importance if he wishes to have a real knowledge of his trade and a living interest in his business, and in these days such training is open to all. The old order, it is true, has changed. The days of apprenticeship, whether for good or ill, are gone for ever, but the intending builder has no lack of efficient substitutes. Thanks to the various technical institutes in London and throughout the country, practical training in all the various building trades lies within his reach at a very slight cost. Many polytechnics have a course of day and evening classes for intending architects and builders, where they can learn both the theory and the practice of their business; and after having been through such a course, the student, though not master of every trade, should be sufficiently acquainted with them to know good construction from bad, and to realise whether the workman in his employ are efficient or the reverse. Perhaps the ideal training for a builder is a course of these technical classes, and at the same time attendance on a building in the course of erection. From the latter he would be able to learn not only how a building is put up from the foundation to the finish, but also to gain some knowledge of the handling of workmen and the general management of a job.

Office Work. With these remarks as to the preliminary training advisable for a builder, our subject naturally falls under two heads—the builder's work in the office and his work outside in supervising and managing his jobs. It is not at all uncommon in building firms where there are two partners for them to divide the duties, one taking entire charge of the estimating work in the office, and the other visiting the contracts in hand, seeing to the ordering of materials as they may be required from day to day, and settling any question that may arise on the work itself. The convenience of this division of labour is quite obvious, but it is not a desirable method to employ. A builder should know all sides of his business, that if need arises—as it is sure to do—he may be capable of dealing with any branch of it. The office work is by far the more important of these two, though the term may be slightly misleading. By it is meant not the mere daily routine of the office, which, with little variation, would be the same in a builder's as in any other, but more specifically preparing estimates and all that has to be done in the attempts to secure contracts. This side of the business presents far greater difficulties to-day than it did twenty years ago. The fight for work and the competition in the building trade becomes fiercer every year; prices are cut to their lowest point, and that not only by those who may be called the "plungers" of the building trade, and in this severe struggle for work scientific pricing of estimates is

often entirely sacrificed, the writer knowing of more than one case where a builder, after making up his estimate, has taken off a good round sum "for luck," as he says. With this increase of competition there must be a corresponding increase in intelligence on the part of the builder if he is to keep his place in the ranks of the successful.

The modern builder must be prepared to face the new conditions, for though some of the severe competition is due to temporary depression, it is in the main due to causes that will probably prove permanent. The public have demanded the cheapness that unlimited competition gives, and architects have been compelled to bow to the popular demand. The builders, too, have themselves to blame in part for this state of things; when tender lists were more select, the work was often too costly, and the inevitable reaction on the part of the building public was bound to come. Under these conditions, the estimating side of a builder's work has become more than ever important and increasingly difficult, and it is no exaggeration to say that it is only after the most assiduous application that skill and certainty in estimating can be obtained.

Invitations to Tender. There are certain kinds of public work that are advertised, and are open to public tender, and there are some builders that almost confine themselves to this kind of work. Speculative work, also, is, of course, open to all builders with capital, or with the ability to borrow capital. But apart from these two classes of contracts, it is difficult, even in these days of competition, for a builder to obtain the opportunity of submitting a tender. Architects, quite naturally, send their work to the men they know, and of whose skill and trustworthiness they have had experience, and unless specially advised, would not include in their lists of "invited to tender" a builder unknown to them; but if recommended to them, architects are not hostile to the young and untried man, and are quite willing to give him the necessary opportunity. For instance, a London architect, with a job outside the London area, would always ask, in addition to his usual list of builders, the local builder to tender, if satisfied of his capacity, because, if for no other reason, he should be able to carry out the work at less cost than his London competitors. The difficulties of obtaining the entrée into the "invited to tender" lists are great, but not impassable, and should not debar any man of capacity from entering business as a builder.

Estimating. A builder may have to estimate for contracts in one of two ways — either from quantities or from drawings, and in the latter case, he will have to take off his own dimensions. In these days quantities are almost always supplied, and it is only in the case of small alteration jobs that a builder should have to take out his own—not many of the principal builders would take out their own in competition for a large contract. It is far easier to estimate from quantities than otherwise; but even then one of the most difficult tasks a builder has to do is to prepare a correct and careful estimate. It is a comparatively simple matter, by low pricing, to secure a contract; but it is much harder to prepare an estimate that will not only secure that, but also show a profit at the end of the job. To all who know anything of the building trade it is common knowledge that there is often a variation of from 20 per cent. to 30 per cent. in the prices of different builders tendering for the same job, and all quantity surveyors can testify how greatly the different prices of different builders vary in detail—some pricing their brickwork low and their joinery high, or vice versâ. This variation can be easily understood if the detailed and many-sided knowledge that is required for accurate pricing is taken into consideration. In the ordinary building there are a dozen or so different trades employed, and the estimating builder must know not only the prices of the various materials needed for these trades delivered to a certain site, but must also have some idea of what the labour on these materials will cost; and it is precisely the latter, or the human element, of which it is so difficult to ascertain the cost.

In passing, it may be remarked that the price book is not to be relied on as a certain guide, although it is very useful for occasional reference. A builder should be able to price the bills of quantities that come to his office from his own first-hand experience; this is not to say that he is never to employ an estimating clerk—most builders do—but it is unwise to depend on him entirely.

Estimating from Quantities. Before beginning to price his bill of quantities, the builder must satisfy himself as to one or two points which might seriously affect the estimate he will be giving. Common-sense will, of course, tell him that building is more expensive in some parts than others—for instance, that in a hilly suburb of London, like Hampstead, it is more costly for him to do work than in the centre of London; all materials would cost more, owing to the heavy cartage, but such knowledge as this he will have from his own general experience. His first business should be to visit the site of the proposed building; he should discover what facilities there will be for the storing of materials—limited space for this purpose will mean increased cost—whether the site is easy of access for carts to draw into, and whether there are any special difficulties connected with it. He should satisfy himself as to the nature of the soil—whether, for instance, it is easy to work or not, and whether sand or ballast can be had from it. Another important point to see to is whether there is likely to be much water met with during the excavations. There is in most bills of quantities a clause to pump or bale out all water met with in the course of the work, and this, in some cases, would amount to a serious item. The estimator having ascertained such points as these on the spot, can return to his estimating with knowledge that will materially help him in his pricing, but before settling down to his work he should call and inspect the drawings, that he may know whether the proposed building is a simple one, or likely to be expensive, because of minute and elaborate detail, the designs of different architects varying considerably in this respect, and appreciably affecting the cost of their work. When beginning the actual pricing of the bills, the builder should have before him the cost of various materials, such as bricks, cement, etc., delivered to the site, and the cost of carting soil and rubbish from the works, this last item varying from 10 per cent. to 15 per cent. in different parts of London. He can sometimes deduct something from the prices thus obtained before tendering, as the merchants are likely to quote him lower prices if he succeeds in obtaining the work.

Fluctuation in Prices. It is the more necessary to obtain such prices, because the cost of some materials varies appreciably—sometimes from month to month. Metals such as lead and iron are very liable to be affected in this way, and if there is a considerable amount of such material in a bill of quantities it is advisable to obtain from the

merchant a price that will be guaranteed for a time sufficient to allow of ordering at that price if the tender should be accepted; otherwise the builder may find himself in serious difficulties. A concrete instance will at once illustrate this. A builder gives in an estimate for a contract in which there are many hundredweights of lead; he comes out lowest in the list of tenders, is accepted for the work, and begins operations about a month after the sending in of his estimate: he will not require his lead either for external or internal work for many months. He has priced this in his estimate at £15 per ton; between the time of sending in his tender and his wanting the lead it has gone up £3 or £4 per ton, and if he has made no contract with his lead merchant at the time of starting his work for lead to be delivered to his works as and when required within twelve months, he stands to lose very heavily on this part of his work. Metals, bricks, cement—the prices of all these are controlled by what are virtually trusts. The builder, therefore, cannot rely on getting lower prices for materials than those he has based his estimate on. The absence of competition makes it certain that the price he will have to pay when he comes to do the work will be the same price he was given by the different merchants when estimating.

Preliminary and Other Items. The preliminary items should be given careful attention in pricing, especially the time given for completing the contract—almost always inserted by surveyors in the bill of quantities—and the time required for maintenance after the building is completed; this varies from three months and upwards and is sometimes as long as twelve months, and can be a very serious item. A case came within the writer's own knowledge where the time for maintenance was eighteen months; the contract was for redraining a large estate, the drains of which had settled owing to the shifting of the ground. The builder was made liable in the contract for damage to the houses on the estate during the time his work was going on, and for eighteen months afterwards for any damage due to the work being carried out; it is obvious that with a treacherous soil this might be a very serious matter for the contractor. Two other items that should be carefully noted are the fees for the district surveyor and local authorities, and for the water required for the works. In the case of alteration to large buildings, should the quantity surveyor not have included a sum for the fees as a provisional amount, the builder would be well advised to write to the district surveyor and ask him what his fees would be. As to water in the London area, the charges are now fixed by Statute, and can be found in any book of reference. The weight of the pipe required for services is the same throughout the London area, but in some cases outside that area the service pipe is required to be heavier even than the London Board's Regulations, and the unwary builder may get caught in this way. In such a case the builder should write for the water company's regulations and requirements.

Specialities and Provisional Amounts. Where bills of quantities contain specialities such as a large amount of granite work or terra-cotta, the estimator should always obtain prices, however experienced he may be; they are quite outside the run of his ordinary knowledge, and it is imprudent to risk making any mistakes—mistakes in estimating are expensive luxuries. However, prices for specialties such as these are often obtained by the architect direct from firms who deal in them, and inserted in the bill of quantities before it is sent to the builder—being known as "provisional" sums. The continued increase in such amounts has been brought about by the great changes in modern building construction and the consequent elaboration in such matters as steel construction, sanitation, and the heating of buildings. The gradual elimination of timber and the substitution of fireproof construction in both floors and roofs has deprived the builder of much of his work, and in some cases reduced him merely to the position of general banker for the contract without any of the usual advantages of that position. For though in the bills of quantities the estimator is always instructed that he must add his profit to such provisional amounts, if he really wants the work he never puts anything on, and all he can be certain of getting out of them is a small cash discount such as 2½ per cent., and this even is not always allowed by the special firms employed.

Closing Remarks on Quantities. The estimator should always carefully read through the headings that precede the bill of every trade; they usually consist of the description and quality of the materials to be used, but there are sometimes items that require pricing and others that call for special attention. There was a bill of quantities within the writer's experience where, included in the headings of the joiner's bill, was a clause that the first instalment on the contract would not be paid until all the doors had been got out and framed together, an item that quite escaped the estimator's notice. If there is any pulling down or any other spot work to be priced this should be done on the site itself; it cannot be properly done in the office. If it is stated that the builder will be allowed to use such of the old materials as are sound and suitable, only a visit to the site and inspection of the existing building and fittings will enable him to tell what credit he should allow under this head. Before finally making up his tender the builder should see the specification and contract. It is true that usually all the items that require pricing are inserted by the surveyor in the bill of quantities, but it is best to make sure. Nowadays, in estimating it is usual to add the profit on each separate item. A better though little used method is to price each item at the prime cost and add a percentage at the end for office expenses, use of machinery, the general superintendence of the job, and for profit. This way is old-fashioned and the modern surveyor is not used to it, but it is to be preferred, for two reasons—it makes pricing more scientific and accurate, and in the case of additions and alterations it certainly tells in the builder's favour to have a definite percentage added on to the whole, especially where there are items for which there is no price in the schedule.

Estimating from Drawings. If estimating where quantities are supplied is difficult, the task is doubly so where there are no quantities and the builder has merely the drawings and the specification to rely on, or in some cases where no drawings are needed, the specification only. Such cases are almost unknown with buildings of any size, and for work exceeding £500 quantities should be taken out.

There are two kinds of work for which it is very usual for a builder to have to estimate without quantities—small alterations and additions to existing buildings, and repairs and decorations. In the case of the first, drawings would be supplied, and from these the builder can get a surveyor to

take off the quantities for him if time should be allowed, though often he has the loan of the drawings only for a day or two; but, in any case, builders of experience would prefer to take off their own quantities, and this is not a difficult matter if the builder has an ordinary working knowledge of drawings and dimensions. He will not do it, of course, with the accuracy and fulness of a surveyor, and his method will be rather rough, but, backed by experience, it will suffice. Without experience, however, the builder had far better go to the small expense of employing a surveyor than blunder along as best he can. Or if this is not feasible, owing to want of time, he had better decline to tender. In the case of repairs and decorations—much the most common—the estimator must take the specification with him to the job in question, and do all pricing there, because a careful examination of the existing work is now considered to be necessary.

Measuring Up. If estimating preliminary to the obtaining of contracts is the most difficult task a builder has before him, a scarcely less difficult one is the measuring up the extras and omissions on the completion of a contract, and settling up the accounts. That no contract is ever completed without extras and omissions is almost a truism. Building operations do not lend themselves to terminological exactitude, and not the most skilful architect or surveyor can foresee all the contingencies that may arise during the course of the work, much less control the changes of mind to which building clients are so liable. The questions arising from these variations in a contract of necessity lead to much discussion between builder and surveyor, and the builder needs tact, judgment, and good temper if he is to deal successfully with them. In addition, there may be also matters arising out of the bills of quantities. The builder may find them deficient in certain particulars, or may think certain items insufficiently described, or the labour to an item not properly taken. In all such matters there is plenty of room for difference of opinion. The builder is naturally anxious to get all that he considers himself legitimately entitled to, and the surveyor is equally concerned to see that the builder does not get more than his rights, though his position is not one of a partisan, but of an umpire—a position from which builders can rely on most quantity surveyors not deviating. Now, in measuring up as in estimating there are two courses open to the builder. He can himself meet the surveyor and go into all the various questions with him, or he can employ another surveyor to act on his behalf. In the case of large contracts there is much to be said for the latter course, or in cases where the builder foresees that acute disputes are inevitable, and that, in consequence, first-class expert advice will be of the utmost help to him; for it may well be that in such circumstances the builder will have neither the time nor the ability adequately to present his own case, and the extra expense of employing a surveyor will be more than justified.

Extras. There are two subjects which are very liable to cause controversy between builders and surveyors—extras, which there is no schedule price to govern, and day work. In the case of the former, when there is any considerable variation—such as, say, the substitution of wainscot for deal in a building, or any large addition to the contract—it is quite usual for the architect to get an estimate from the builder before ordering the work, a preferable method to leaving it to be settled at the end of the contract, and fairer both to the client and the builder. Where the variation is slight, and no estimate is given—and most contracts will show some few items for which there is no schedule price—compromise as to price ought not to be difficult. The usual method is for the surveyor to price out the extra and omission bills, and forward them to the builder for his approval. He may put the prices too low, anticipating that the builder will ask too much; but in most cases the builder will find himself able to accept as fair the prices offered, and will always find the surveyor open to conviction if he can prove that any particular item has been priced below its real value. For it is not the unfairness or partiality of a surveyor that the builder has to be on his guard against, but the ignorance that arises from knowledge gained by theory instead of practice. The writer has in mind one particular instance of this. The taking down of a door, easing, adjusting, and rehanging in the same position was priced by a surveyor at 1s. 3d. The builder would want 3s. for it; the surveyor might say that, theoretically, a carpenter should do the work at this price, but the builder would know from practice that not a carpenter could be found in London to do the work for 1s. 3d.

Day Work. But a more fertile cause of difference of opinion than extras outside the schedule price is the question of day work. There is not much difficulty about the actual prices—for, to most contracts there is a schedule for day work attached—but as to what kind of work a builder is entitled to charge under this head. Where the builder claims day work, the usual custom is for him to send into the architect weekly vouchers of the time and materials. Sometimes the architect will accept these outright, but more usually with the proviso that the surveyor must go into them at the conclusion and decide whether the work in question can be measured or not. Where there is a clerk of the works, he has to sign the weekly sheets; and where this is done, and the architect has accepted them, the builder should not forgo his claim to have this treated as day work; the surveyor has then no right to an opinion on the matter. But when, at the end of the contract, the day-sheets are handed over to the surveyor for adjudication, the builder must satisfy him as to the reasonableness of his claims. Some surveyors, unwilling to admit any limitation in their own profession, are too apt to think that any and every kind of work can be measured. Should the builder have the misfortune to meet such a surveyor, he must decide what he has a right to charge day work, and insist on his rights. A builder's claim to day work may be based either on the nature of the work itself or the conditions under which it is carried out. Under the first head would come such work as the cutting away for hot-water fittings, unless the builder has to take the risk himself.

There is, for example, a provisional amount inserted for hot-water work, and sometimes the general contractor has to do the necessary cutting away for the fitters and to price the item as he thinks best; but more frequently there is a provisional amount also for the cutting away, and the builder returns what he does under this as day work. It is obviously impossible to measure a hole cut in one place and a hole made good in another. Under this head, too, would come alteration to work already done, such as alteration to drainage already laid. Where the day work claim is due to the conditions under which the builder has to work, it is advisable for him, before doing the work, to point out to the architect that he cannot do it at

the ordinary contract rate, always, of course, presuming that there is no clause in the contract to cover work under such conditions. Work of this kind would be, for example, that done to the interior of a school while in occupation of the children, where the builder has to do the work as best he can, and to suit the convenience of the teachers; and where the builder is not required by his contract to work under these conditions, he is quite entitled to charge it day work.

Excess and Deficiency. Before leaving the question of settling accounts, one other matter must be touched upon—the excess or deficiency of quantities. Bills of quantities can either form part of the contract or not. In the latter case the builder's claim, if he thinks there is a deficiency in some particular, would lie against the surveyor who had taken out the bills. Where the quantities form part of the contract, which is the usual course, the surveyor, when measuring up, will not raise the question of excess or deficiency, presuming that the quantities are correct, but will leave it to the contractor to make a claim if he wishes. But the builder will be advised to be very careful before he makes such a claim. Nowadays, quantity surveyors are scientifically accurate, and the contractor, unless he should discover any considerable omission, will not find it worth his while to raise questions on small points which, while involving much labour, will bear little practical fruit. In this matter the builder will do well to restrain the zeal of his foreman. Many foremen, when a job is being measured up, are eager to point out that the quantities are short in this or that particular, without, of course, having gone into the general question whether it is worth while to raise the question of quantities, and a foreman should always be advised to refer such points for the contractor's consideration and decision. One other point the builder must be prepared to meet—the accuracy of his own prices in the bills. This will arise only in the case of extras and omissions. For example, suppose there is an amount of galvanised iron tongue in the bills taken out per foot run, priced by the builder, probably in clerical error, at 1s. 6d. per foot instead of 1½d. On the completion of the job there is found to be a large quantity extra, and the surveyor will wish to price this quantity at the usual price. The builder must here stand firm—the bills of quantities form a schedule that must not be departed from, whether the error is in his favour or not. If it had been against him, the surveyor would have shown no mercy. Of course, in some cases, errors of this kind are detected, when the builder deposits his priced-out copy of the bills with the surveyor, and in that case he is asked to correct the error without, of course, altering the total of the contract sum.

Outside Work. It remains very briefly to consider the work that a builder has to do in supervising and managing the contracts he has in hand. This side of his work, though second in importance, can be by no means lightly regarded. The great quality he will require, whether dealing with the client or the architect or his own workmen, is the quality of tact. Personality tells here more than on the other side of his business, and the possession of tact may make all the difference to the keeping or losing of a connection. The jobs on hand should be visited frequently, so that the builder may see for himself that satisfactory progress is being made, and that if any difficulties arise he may have immediate knowledge of them. One of his most necessary equipments will be a thorough practical knowledge. Questions may arise any day as to the best and safest way of carrying out his work when the knowledge of his foreman will need to be supplemented or corrected by his own. The foreman may be inclined to sacrifice safety to speed, and needs at times a restraining hand in this direction. The architect may require advice at times as to the best construction to be used, and though, should anything happen to the building through faulty construction, the first responsibility is the architect's, the builder would not be guiltless of contributory negligence if through ignorance or carelessness he had failed to see what was amiss. Then the builder should have some acquaintance with the Building Acts and the various by-laws of the central and local authorities. The responsibility of meeting their requirements is always thrown upon his shoulders, and his task is not rendered any more easy by the anomalies and inconsistencies of which they are full. His more immediate duty on his visits will be to see that the jobs are being kept well supplied with materials. In this matter he should be very careful to look ahead. Foremen are too apt to imagine that if they give an order it can be executed the next day: but the builder who waits for his foreman to order the material will find his jobs standing still for lack of them, and it often means that, while waiting, men have to be taken off from one piece of work and put on to another—a very ready way of mounting up the cost of a job.

Defective Materials. Then he will be sure at times to have to deal with the question of bad material. He will come round to his job one day to learn that the clerk of the works has condemned the bricks or timber as not being up to specification, and he will have to determine promptly by personal inspection whether the clerk of the works is justified or whether he thinks the material good enough to defend. In the case of bricks it is usual to deposit with the architect at the beginning of a job a fair average sample of the bricks to be used, and by this sample the builder should bind his brick merchant, ordering his bricks from it. This course allows a fairly wide latitude, for bricks must be judged in the bulk, and what the builder has to determine is whether the bricks condemned have been so because of a few bad ones, or because they are, as a whole, below sample. In the latter case he is without defence, and he will be well advised if he has one load of bricks condemned to warn his foreman not to take in any more of them on the job unless they are up to sample. His position with the brick merchant, if the bricks are really bad, will be much stronger if he refuses to have them unloaded.

The question of timber will be a far more difficult one. It is usually specified to come from certain ports—in some cases, even, from ports whence timber has ceased to be imported for several years. The builder's best course is to inspect the timber in the docks before he buys it, and satisfy himself that it is up to his requirements. But really good timber is getting scarcer and dearer every year, and he will often have to be satisfied with the second best. If his timber is condemned and he is convinced that he cannot defend it, his best course is to take it off the job at once. That is not to say that he is always to give in; for if he have the misfortune to meet with a clerk of the works who has a passion for condemning everything both in material and workmanship it will be advisable to take up a firm stand from the first.

Speed of Work. But above all, the builder should carefully watch the progress of his jobs, and see that he is not getting behind his contract

time. It is true that penalties for time are rarely enforced, because there are so many contributory causes of delay—besides, possibly, the builder's lack of energy—that enforcement is found impossible in practice; but, in any case, slow work in these days is bad for the builder's reputation, and his pocket. It is a matter for discussion whether buildings were not better built when they were erected calmly and without hurry than they are in these days of rush. But the builder today has no time to stop and discuss this; he must move with the times, or he will soon cease to do building at all. But while taking care that his jobs are being pushed on as rapidly as possible, he must see to it that they are not crowded with men, or his cost book will be anything but pleasant reading. Besides his ordinary visits the builder should make a point of sometimes visiting his jobs at the time of starting in the morning; foremen want keeping up to the mark in the matter of time, and a late foreman means little work done before breakfast.

Foremen. The choice of the right men to carry out his work is a matter of great importance to the builder, and very much depends on the foremen he employs. The chief requisite in a foreman is the capable management of men; he must not only have a first-rate knowledge of the best means of carrying out work, but he must also be able to drive his workmen and get the most out of them he can, consistent with safe construction; and for this reason a foreman should be allowed a free hand in the choice of his men, with a few obvious limitations. Should a man be taken on at a job whom the employer, from previous experience, knows to be a bad workman, the builder must, of course, tell his foreman that he cannot have the man on his works; but apart from such exceptions the builder should not interfere with the men the foreman chooses, and if he has cause to feel dissatisfied with the men employed on the job, and should the results convert that feeling into conviction, the only way is to get rid of the foreman. It is almost unnecessary to say that a foreman must be sober and honest, straight not only to his employer, but to his employer's clients. A man who is dishonest towards the clients will, in the end, be dishonest towards his own employer. A builder should see that he makes his own interests and the foreman's identical; this can be assured by giving the foreman continuous employment, and keeping him on even if for the moment another job cannot be found for him.

Bonuses. Another method by which a foreman can be induced to take a serious interest in his work is by offering him a bonus at the end of the job should it come out on the right side; but this wants careful consideration, and special care should be given to the foreman's character if this bonus is offered. In these days of cutting prices, where work is too often taken below cost price, it is a temptation to a foreman to make the job pay by scamping the work. How far should a foreman be trusted is a question that builders are always having to put to themselves. Should a foreman be allowed to pay wages himself, or ought it to be the invariable rule that somebody from the office should pay? In the case of small contracts, where the wages are not heavy, the foreman may be trusted to pay, but only, of course, provided that the builder has had him in his employ for some time, and is convinced of his trustworthiness and honesty. But with contracts of any size, it is the rule for the builder himself or a clerk from his office to pay at the job. One other piece of advice may be useful—don't dismiss your foreman for trivial reasons. The old-fashioned method was to send a man away at once if you had the slightest disagreement with him; that method is happily passing away, experience having proved that a man who is always in fear of dismissal does not make a good servant.

Employer and Workmen. The growth of trades unionism and the combination of both masters and men had led to the hope that the development of better feeling between employers and workmen thus engendered would reduce to a minimum the danger of strikes. This hope has not been realised, and the building trade, like many others, has suffered during the last year or two from spasmodic and unauthorised strikes. Such outbreaks are often due to temper on both sides rather than to any grievance that could not be dealt with in the council chamber; and it is to be hoped that their folly and uselessness will lead to their abandonment as a method of settling disputes between capital and labour.

The Attractions of the Building Trade. It may, perhaps, be asked, can building, under modern conditions and modern competition, be made to pay? There is no reason to the contrary if the builder will face these modern conditions with courage and wisdom, and not be in too much of a hurry to get rich. It ought to be an axiom, but is not, that no builder should take work below cost price; and if for the time he finds it impossible to compete with modern prices, he had better hold his hand. It is better to play in the streets than work at a loss, and continual lowering of prices will tell its own tale in the Bankruptcy Court. Let him keep his head, get what little work he can at a fair profit, and not plunge by taking large contracts at impossible prices.

With all its drawbacks, one charge cannot be brought against the building trade—lack of interest. At the end of most careers a man can only point to the amount of money he has made as evidence of his work. The builder leaves a far more enduring mark behind him; and though not, of course, sharing the artistic honours that fall to the architect, he is essential to his work, for without him the architect's ideas would find no permanent or concrete expression. For this reason, to say nothing of others, no builder who honours his business should consent to have anything to do with scamping methods, or to take work at so low a price that no profit can be made without seriously deviating from fair workmanship. And here architects may well be asked to lend a helping hand by refusing to hold out to their clients delusive hopes as to how cheap work can be done.

Building Abroad. In the details of building operations and methods there is room for much diversity, and practice is regulated by climate, customs, and materials.

This course has of necessity, in considering the detailed methods of building construction, dealt with their execution as carried out in England. To a great extent, in many of the trades the practice is much the same in the whole of Greater Britain and America; and either an architect or a builder who had received an efficient training in his own country, though he would find—especially in the details of practice—divergencies from what he was accustomed to, would in a very short time readily adapt himself to them.

WIRELESS TELEGRAPHY

WIRELESS telegraphy, or radio-telegraphy, is a system of signalling from place to place without connecting wires, and is accomplished by means of electric—or Hertzian—waves, propagated through a medium termed the ether.

The problem confronting electrical engineers has been to devise apparatus capable of sending out or transmitting electric waves through the ether, and of collecting, receiving, or detecting at a distance the waves so sent out.

Hertz's Discovery. The first step in this direction was taken by Heinrich Hertz. In 1879 the Berlin Academy of Science offered a prize for researches into certain effects of electromagnetic forces, and Heinrich Hertz, the man who "discovered" wireless telegraphy, made some experiments—the principles of which Mr. Marconi was the first to apply to actual practice—in this connection which ultimately led to his causing electrical discharges in Leyden jars to be responded to or "answered" by similar Leyden jars between which there was no connecting wire. The famous researches of Hertz began about 1887, and later he produced an oscillator which sent out ether waves that were received and responded to by a resonator—the germ of the tuned sending and receiving stations of today. [See page 3592.]

The Commercial Development of Wireless. The discovery by Branly of the coherer was the forerunner of the first commercial means of receiving wireless signals, and for some years improved coherers were used in the receiving apparatus of the various Marconi stations.

The work of Ducretet, of Paris, who pointed out the importance of having the sending and receiving stations tuned by means of inductances, was a great forward step in promoting efficiency; and then the efficiency of transmission and the delicacy of reception improved by leaps and bounds, owing to the splendid work of Mr. Marconi and the various scientists and engineers who concentrated their attention on wireless matters.

The work of Sir Oliver Lodge, Professor Branly, and the many other scientists who carried out experiments with electric waves all contributed to progress, and have proved of immense value. But from a practical or commercial standpoint we must consider the beginning of wireless as dating from 1896, when Mr. Marconi first came to England and carried out his experiments at Westbourne Park. A year later he gave a demonstration on Salisbury Plain, carrying out communication over a distance of four miles. In December, 1898, the distance was increased to twelve miles, and in 1899 to thirty-six miles. Two years later, Mr. Marconi succeeded in signalling to St. John's, Newfoundland, from the Poldhu station, in Cornwall, a distance of 1800 miles; and recently he received signals, on a vessel fitted with a high aerial wire suspended from a kite, over a distance of 6000 miles.

The progress that has taken place, however, is not by any means confined to the distances involved; the methods, apparatus, and, above all, the efficiency obtained nowadays make the progress of this new science seem almost phenomenal. Today we telegraph by wireless from aeroplanes, airships, trains, submarines, and mines; we can work "duplex"—that is, send two messages simultaneously over the same apparatus—while the knowledge we have of the mysteries of wireless is extraordinarily detailed, though by no means complete.

There are, of course, various systems at work, the Marconi system being the foremost, but the Australian Commonwealth has its own system; the Danish system of Poulsen is at work at the Panama Canal, and there are various methods of wireless at work in America, France, Germany, and Italy. The principal features of the chief systems are briefly described in this course.

Hertzian Waves. The most important of Hertz's experiments, from our point of view, was that by which he proved the existence of radiation. The reader of the course on ELECTRICITY will recall that he fixed two metal balls near one another [Fig. 258, page 3595], and the balls were each connected by rods to a metal plate or sphere, which acted as the coatings of a condenser [see page 3350]. By applying positive electricity to one plate and negative electricity to the other, the plates were each more and more charged with electricity until they broke down the air-resistance between the balls, and a spark flew across the gap. It has been explained in page 3475 that when a condenser is suddenly discharged, the effect is oscillatory, and after the first passage of electricity each plate or sphere becomes charged with the opposite kind of electricity, and this is again discharged, and so on. The electric charge rushing backward and forward in this way is due to the rapid vibrations of free electrons, and any oscillatory movement of electrons results in the setting in motion of the ether. This motion is a *wave-motion*.

Hertz was able in the course of his experiments to discover this wave-motion, and subsequently to show how interference could take place as it does with light-waves. He used a ring of wire split at one point, the two free ends terminating in little balls [1]. When the oscillator above described was at work, Hertz found that the ring resonator would respond, and that

electrical vibrations would be set up in it, which caused tiny sparks to fly across the gap between the little balls.

The Ether a Medium for Wave-Motion. The ether, or æther [see page 740,] may be defined as that infinitely tenuous medium which fills all interstellar space and permeates all matter. It cannot be isolated or detected in any direct manner, but it is known to be inert and elastic, offering very little frictional resistance to heavenly bodies, and permitting the transmission of light, heat, and electric waves from the sun to the earth in about eight minutes. The ether is essentially a non-conductor, or dielectric, for these electric waves cannot travel in a conductor, and therefore cannot be propagated through water, and only indifferently through earth or rock; but through brick walls, wood, stone, and similar non-conductors which shut out sound and light, wireless waves and disturbances are able to travel.

Any disturbance in an elastic medium causes a wave-motion, which travels away from the point of disturbance through the medium.

Wave Motion. If a pebble is dropped into water, a circular ripple is caused, and this ripple travels along, going outwards in all directions, so that the circle quickly increases in size. The water acts as a medium through which the wave-motion is propagated.

The ether is the medium which, in the case of wireless telegraphy, replaces the water in the case of the ripple; the wave-motion is set up and produced by the oscillatory agitation of the electrons, as the experiments of Hertz showed, and this wave-motion, electro-magnetic in character, takes place in the ether, the waves travelling at about the same rate as light—that is, about 185,000 miles a second. They can also be reflected like light-waves, for Hertz found that by reflection he could get a "crest" of one wave to interfere with the "hollow" of another, and so prevent his ring resonator from sparking.

Professor Fleming has aptly described electrons as strain-forms or centres from which twists start, and the energy exerted by a twist is propagated through the ether. Very rapid alternations of electric current, such as we are dealing with in wireless telegraphy, cause the electrons to jump backward and forward with great rapidity, and the shock resulting will cause vibrations that will carry energy through the ether for long distances. A piece of elastic extended and let go of gently will do nothing, but if pulled out of shape and suddenly released it will produce great energy, as in the case of a catapult. The ether disturbances produced by the sudden electrical discharge of the condenser and the sudden "twistings" of the ether are somewhat analagous.

Measurement of Waves. In any train of waves the *length of a wave* is the distance between any point in that wave and a corresponding point in the wave behind or before it. Thus, for instance, the distance between the crest of one wave and the crest of the next is the length. This is commonly indicated by λ, and measured in metres.

A complete wave is measured from crest to crest, and the *amplitude*, indicated by a (Greek *alpha*) is the perpendicular distance from the highest point of the crest to the lowest point of the trough. The number of complete movements of a wave, or oscillations per second, is termed its *frequency*.

It must be noted that though the amplitude of a wave is steadily decreasing as the distance from the point of origin increases, the length of the wave remains the same, whatever its distance from that point. The speed, too, remains the same, whatever the size of the waves.

The velocity of a wave is the product of the number of oscillations per second and the wave-length. Thus:

$$V = n\lambda$$

where V = the velocity in metres, n = the number of oscillations per second, and λ = the wave-length in metres.

The behaviour of waves will be readily understood if we return to the experiment of the stone being dropped into a pond, and watch the outward travel of the ripples: we see that they gradually become smaller, and finally die out. The ether waves behave in the same manner, as, by travelling outward and thus spreading, their energy is distributed over an ever-increasing area, quite apart from the question of the energy being absorbed or dissipated in other ways. Taking the water-ripple as analagous, its *amplitude* would be measured by the maximum distance between the top of a crest and the bottom of the corresponding hollow—that is, AB in Fig. **4**. The amplitude of the next wave, CD, would be less, and so on until the wave died out.

The amplitude of the electro-magnetic wave similarly decreases, and the ratio of the successive amplitudes give us the *decrement*. At each discharge of the aerial a group of oscillations is sent out, and the number of waves in a *train* depends on the decrement.

Symbols. In diagrams illustrating wireless telegraphy circuits, a number of symbols are used to indicate the component parts of the apparatus. The more important of these are illustrated in the accompanying diagram [6].

The Induction Coil. Modern wireless telegraphy depends upon the radiations or ether-waves sent out into space from an aerial wire, or antenna. High voltages are employed, and these voltages are obtained by transforming up the low-voltage currents ordinarily obtainable. The most usual transformer, though not the most efficient, is the induction or Ruhmkorff coil, and it is used in many ship-stations, in the emergency sets on large ships, and almost invariably by amateurs for their private stations

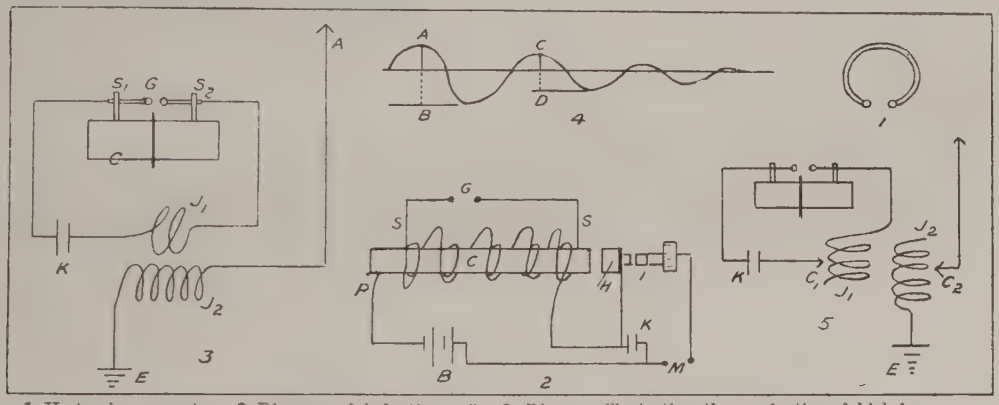
The induction coil consists essentially of an iron core, round which are wound two coils, one of thick wire and few turns—the *primary*—the other of very fine wire of many hundreds of thousands of turns—the *secondary*—and a means of rapidly and abruptly interrupting the current flowing through the primary coil. In the case of a coil such as would be used on board a ship, capable of giving a spark ten inches in length between the secondary terminals, we

should find the core, or bundle of fine iron wires, wound round with two, or perhaps three or four, layers of thick, insulated copper wire; over this a thick ebonite tube, and over the tube perhaps ten miles of fine, silk-covered copper wire. The secondary coil is wound in several sections, and is thoroughly impregnated with paraffin wax in order to render the insulation sufficient to withstand breakdown. In many modern coils the primary is also divided, and the different layers can be coupled up in parallel or series, according to the type of spark required.

The induction coil is shown diagrammatically in Fig. 2. B is a battery supplying current to the primary coil, PP, wound round the iron core, C. SS is the secondary coil, and G the spark-gap. I is the interrupter, on the smooth running and regulation of which much depends in wireless work. M represents the Morse key. When M is tapped, contact is made and current flows through the primary via the interrupter. H is a hammer of iron, which is now attracted by the core, C, which is magnetised owing to the current in the primary. On H being attracted, however, contact is broken at I, the magnetisation ceases, and H flies back again, contact is remade, and so on. K is a condenser, usually of about two microfarads capacity, consisting of alternate layers of tinfoil and varnished paper. At each interruption of the current the number of linkages of lines of force is varied, and an induced electro motive force is produced in the primary tending to oppose the change of current. The important effect of the condenser is to take up the induced electromotive force, and thus interrupt the primary current more suddenly. As a result, a higher electromotive force is induced in the secondary. The condenser, besides accelerating the break of the primary circuit and holding back the current when contact is made at I, greatly helps to eliminate sparking at the contacts I.

In using an induction coil for wireless work, these contacts must be frequently filed flat, as the sparking produces burning and liability of fusion and resultant short-circuiting.

We shall now see how, with the high voltage produced by the induction coil, we are able to produce the high-frequency oscillations necessary to produce ether-waves. In Fig. 3, C represents the induction coil, S_1 and S_2 representing the terminals of the secondary coil. G is the spark-gap; and if we assume that the coil is capable of giving a ten-inch spark in air, the brass balls of the spark-gap would probably be placed about one inch or one inch and a half apart, as the oscillatory spark used in wireless is far more intense and much shorter. The spark-gap is connected in shunt with a condenser, K, and an inductance J_1, the latter consisting of two or three turns of heavy copper or aluminium wire about a foot or more in diameter. When the induction coil is operated by the key, a spark flies across the gap G, and the condenser K discharges itself, and, the discharge being oscillatory, a very rapid series of sparks takes place, the time (T) between each maximum charge of the condenser being given by $2\pi\sqrt{LC}$, where C is the capacity of the jar and L the self-induction of the coil J_1. The coil J_2, consisting of several turns of wire of smaller gauge than J_1, is inductively

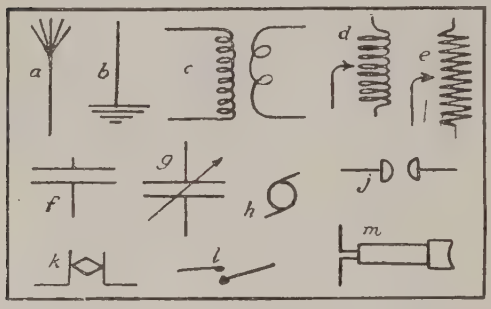


1. Hertz ring resonator 2. Diagram of induction coil 3. Diagram illustrating the production of high-frequency oscillations 4. Diagram illustrating the amplitude of waves 5. Diagram illustrating alteration of wave length

effected, and the electric oscillations of the primary circuit are imparted to the secondary circuit, this consisting of the coil J_2, the aerial wire A, and the "earth," E. This circuit, the capacity and inductance ($L \times C$) of which must be equal to, or a simple multiple of, the LC of the primary circuit, is excited by the latter, and electromagnetic waves are set up in the ether by the rapid alternations of potential along the aerial A. The condition for the discharge of the primary circuit being oscillatory is that its resistance must not be greater than $\sqrt{\frac{4L}{C}}$

Wave Length. Wave length is dependent on the frequency of the oscillations. The frequency can be measured, or it can be calculated from a known expression, $n = 160{,}000/\sqrt{CL}$, C being measured in microfarads and L in microhenries; if we call it n, then assuming the ether-waves to be propagated with the same velocity as light—say, 185,000 miles or 300,000,000 metres per second—we can find the wave length from the formula for wave velocity previously quoted, by dividing this velocity by n. In other words, the wave length $\lambda = \frac{300{,}000{,}000}{n}$ metres. It will be

seen that the greater frequency of the oscillation, the shorter is the wave length. The longest wave made by Hertz in his experiments was about nine metres, but with modern apparatus waves of about 9000 metres have been produced. The wave length generally employed today in ship and shore station equipments is 300 or 600 metres, but special stations for long-distance work use waves varying from 1000 to 8000 metres in length. The path of these waves is probably in a non-conducting atmosphere between the surface of the earth and a boundary some thirty or forty miles above it.



6. SYMBOLS USED IN WIRELESS TELEGRAPHY

a, aerial wire or antenna; *b*, earth connection; *c*, induction coil or transformer; *d*, coil in which the inductance can be varied; *e*, coil in which the resistance can be varied; *f*, condenser having quality of capacity; *g*, condenser of variable capacity; *h*, direct current dynamo; *j*, spark-gap; *k*, crystal detector; *l*, Morse key; *m*, telephone

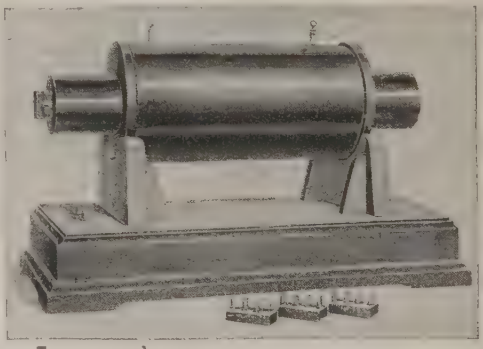
Alteration of Wave Length. We have seen that the wave length λ depends on the capacity and inductance involved. Hence, by varying these factors, we are able to change the wave length. Thus in Fig. 5 C_1 and C_2 are sliding contacts arranged so that C_1 can be attached to different turns in the primary inductance, thus allowing a different amount of inductance to be included in the oscillatory circuit. C_2 can similarly be coupled up with different turns in the secondary inductance, as whenever J_1 is varied, J_2 must be varied in order to get the two circuits into resonance.

The Aerial and its Function. We have already made mention of the *aerial* and the *earth*. The aerial, or antenna, has two functions—to transfer the energy of the transmitter to the ether in the form of electric waves, or to absorb or collect it from the ether for use in the receiver. It consists sometimes of a single wire, but more generally of parallel wires or a system of wires (radiating, perhaps, in the manner of umbrella ribs) supported by a mast high above the ground and well insulated at the supports with ebonite, porcelain, or some other suitable substance, the end being attached to one side of the spark-gap of the induction coil or to one end of the inductance coil. Stranded copper or bronze wire, size 7/20, makes a good aerial. It may be protected from the weather and its capacity increased by an enamel.

The form the aerial takes is, of course, largely dictated by the area at disposal. A single air-wire held by an insulator from a mast is of little use except for very short distance work. The form largely favoured in medium-powered stations is two or more wires in parallel between two masts. By increasing the number of wires in an aerial the capacity is increased, but to secure the increased capacity that parallel wires give they should be well separated. The higher they can be placed above the ground the better, 30 ft. being not too high for a small station. The sectional steel masts of long-distance stations tower 200 to 450 ft. above the earth. The distance between the masts should also be long—over 100 ft., if possible, for a small station—for the longer the wires the greater the inductance of the aerial.

At the coast stations of the Marconi system there is usually one high central mast, with an umbrella aerial connected to four subsidiary masts. This permits good, all-round working. But where communication is desired in a special direction two or more masts are used, placed in positions best suited to the employment of the directive aerial principle [see later]. On board ship the usual fashion is to suspend the wires horizontally between the masts.

Earthing. Whether an aerial should be *earthed* or not has provoked considerable discussion. Earthing is adopted in all Marconi stations; indeed, "the most important feature of Mr. Marconi's first patent was the earthed aerial—that is, the aerial connected to ground directly or through capacity, so that by virtue of the conductivity of the earth's surface, and the consequent imaginary aerial therein, the true aerial became twice as effective as that of a similar aerial entirely dependent on the earth's surface." Generally, an earth connection is made by laying a number of wires



7. WATSON'S INTENSIFIED INDUCTION COIL

or copper strips just under the ground, radiating in all directions—the farther the better—from the station. A connection is formed at the junction of the wires, and leads into the station, where it is attached to the side of the spark-gap opposite to that which is connected to the air-wire, or to the end of the inductance as shown in Fig. 5. In the earth employed in Marconi stations conducting plates are symmetrically placed round the station and connected up by radial conductors, the power of the station and the nature of the ground determining the extent of the earth. In some cases, such as

military stations, where the character of the ground makes it a matter of difficulty to bury the earth, wires or wire netting may be simply laid or stretched over the ground, and connected to the earth side of the transmitting or receiving apparatus. After this manner is the Fessenden "wave-chute," an American invention. On

board ship earthing is effected by connecting to the hull of the vessel.

Briefly, it may be said that it is claimed for earthing that it greatly increases the distance over which messages can be sent and received though Sir Oliver Lodge contends that the, earthing of an antenna militates against sharp tuning.

Directing the Waves. The waves travelling from the antennæ radiate over the earth's surface much as the water falls round a fountain on a still day. Consequently, if communication is taking place between two stations only, a great deal of the energy which it is desired to confine to a particular route is wasted. The problem thus arose of keeping the waves to a definite path, like the rays of light directed from a searchlight.

Hertz, using waves two or three feet in length, demonstrated that cylindrical parabolic mirrors caused electric radiations from an oscillator to be reflected and converged; and Marconi, over a short distance on Salisbury Plain, was successful in focussing such a beam on a distant station, the application of the idea being a feature of his first British patent in wireless telegraphy. It is essential, in the case of wave motion, that the mirror be large in comparison with the wave length; and hence, as the wave lengths necessary to cover long distances must be large—possibly up to several hundred metres—the use of mirrors becomes quite impracticable for the purpose of reflecting and converging them.

Marconi, in the course of his experiments, noticed that if the vertical air-wire is bent at the top parallel to the ground, the waves are sent out most strongly in the direction opposite to which the wire is bent; or, taking the letter T as an illustration, if the wire is bent to the left arm of the T, the greatest wave-flow is in the direction of the right arm of the T, and vice versa. This is the principle of the Marconi *directive aerial*. Marconi also found that if the receiving antenna is bent in a direction away from which a message is coming, the signals are greatly improved in strength. Therefore two stations are in the best condition for intercommunication when their antennæ point in opposite directions. The explanation of Marconi's discovery is that the lines of magnetic force stretch out farther into the ether in the direction opposite to which the antennæ point, and so give the greatest radiation in that direction. The area of minimum radiation is approximately at right angles to the line of maximum radiation.

The method of finding the direction from which signals are arriving is dealt with later.

Damped and Undamped Waves. Every wireless system aims at the transmission of more or less continuous waves, as the greatest efficiency is obtained in this way. But a very large number of stations working at the present time depend on either an induction coil or a high-tension transformer to produce the high-tension current; and the electric waves produced by these methods are not continuous. A series of short wave-trains are sent out from the aerial or antenna, and these waves are *damped*—that is, each wave-train rapidly dies out. If, however, one wave-train follows the next with very great rapidity, the result tends to become equivalent to a persistent train of waves, and this effect is very successfully produced in the larger Marconi apparatus as used for long-distance transmission.

The Transmitter. The simplest type of wireless transmitter is that dependent on an induction coil, such as is used in the Marconi

"emergency set." The induction coil is supplied with current from a battery of accumulators, and in the emergency set is used simply in connection with the aerial—that is, without a transformer. But a large number of stations are equipped with a coil, condenser, and transformer,

and are capable of a range of about fifty miles by day, and considerably more by night. In larger stations the induction coil is replaced by a static transformer [8]; the secondary of the transformer is connected with the fixed type discharger shown in **9**.

The Oscillation Transformer. The transformer, often known as a *jigger*, plays a very important part, not only in the tuning, but in getting the circuit shunted off the spark-gap into resonance with the circuit comprising the aerial and "earth." In Fig. **10** the spark gap, S, is shown connected up in the circuit containing the condenser, K, and the inductance coil, J_1. J_2 is another coil, of more turns of thinner wire, and J_1 and J_2 form respectively the primary and secondary coils of the *high-frequency transformer*.

Iron cores greatly increase the efficiency of transformers, by increasing the intensity of the field, as will be gathered from the chapter on Transformers in ELECTRICITY. But here the high frequency of the currents and the *hysteresis* of the iron—its tendency to be slow or to "lag" in becoming magnetised when the magnetising force is at its maximum, and similarly to lag in losing its magnetism when that force is reduced to zero—render the use of iron impossible, so that the wireless transformer resolves itself into two simple coils, separated by an air space, and placed closer together or farther apart according to the nature of the coupling desired. *Coupling* denotes the proximity of the coils to one another; it is *loose* if the coils are far apart, and *tight* if they are close together. One coil, the primary, may consist of two or three turns of wire, perhaps 18 in. in diameter; the secondary of five to twenty turns of thinner wire, of the same diameter.

In Fig. **11** is seen an *auto-transformer*—that is, one coil only is used, *xy*, representing the primary, and *zy* the secondary. This is the tightest coupling possible.

For the greatest amount of current to be induced in the secondary, the oscillation constants of the primary and secondary circuits require to be equal. Thus, as the *oscillation constant* (O) depends on the product of the capacity of the condenser and the inductance in the circuit ($K \times L$), it can be varied by varying the condenser, K, or the number of turns in J_1. Or if K and J_1 are fixed, we can vary J_2. The aerial, A, has, of course, both inductance and capacity.

When the two circuits are in resonance [see page 3475], the maximum effect will be produced. If an incandescent lamp be placed (shunted) across a part of the secondary circuit, and K or J_1 be varied, it will be found that the lamp will glow with varying degrees of brightness; the glow will be brightest when good resonance has been obtained.

Aerials and Wave-lengths. The natural wave-length of the aerial is something between four and five times the actual length of the aerial. Where, as is often the case with small experimental stations, the aerial cannot be made very long, a good deal of inductance in the secondary of the transformer has to be introduced; thus in Fig. **10** the number of turns in J_2 would be increased. Where, on the other hand, the aerial is too long for the wave-length in use, as is sometimes the case in big ships when working temporarily on a short wave, it is necessary to put a condenser in series with the aerial, so as to *decrease* its capacity, thereby increasing the oscillation frequency. The velocity of the waves, V, is fixed (185,000 miles per second), and is equal to the product of the wave-length and frequency of the oscillations, according to the equation $V = n\lambda$, but as $n = \frac{1}{2\pi\sqrt{LC}}$ anything that is done to lessen the inductance or the capacity will increase the frequency, and lessen the wave-length.

Coupling for Sharp Tuning. The coupling of the primary and secondary of the transformer is an important matter, as when correctly arranged the tendency to emit two distinct wave-lengths which exists is minimised. The looser the coupling—that is, the less inductive effect of the primary on the secondary—the greater is the *selectivity*; or, in other words, the sharper the tune obtained. This sharpness, being obtained at the expense of the inductive effect, is bad from the point of view of efficiency, and the radiations emitted by the aerial are weak. When the maximum radiation is required, the coupling must be close, although the tune of the waves will not then be so sharp, and interference by another transmitter is less easy to avoid.

The coupling is varied very ingeniously in some transmitters by means of a hinged pair of coils. One arrangement is shown in Fig. **12**, where J_1 is the primary, J_2 the secondary, and S is a side-strut by which the two can be clamped at any desired angle.

Quenched Sparks. As regards the actual form of the transformer, it has been found that there is no advantage in having more than one turn of wire in the primary coil, though two are often used. The secondary coil usually consists, in the Marconi transformer, of five to twenty turns. In a closely coupled transformer the secondary is usually wound over or under the primary, and to secure good insulation the whole transformer is sometimes immersed in oil. With close coupling and good radiation resulting, there is, as already observed, the trouble that waves of two frequencies are produced; and as only one is detected and used in an ordinary receiving-station, there is a loss of energy.

This dual frequency, resulting from the inductive effect on the *primary* of the current induced *by* the primary in the secondary, has been successfully eliminated by means of what is known as *shock excitation*. Rapidly *quenched* sparks in the primary circuit have been found to produce rapidly recurring trains of oscillations in the secondary of a uniform, and not dual, wave-length. The oscillations in the primary circuit, owing to the quenched spark, are damped out too rapidly for the reaction between secondary on primary to take place.

The quenched spark is a feature of many modern systems of wireless telegraphy. A blast of air across the spark-gap, for example, will blow away the conductive gases produced by the spark, increase intensely the resistance of the gap, and prevent the recurrence of the spark, and thereby the oscillatory effects on the primary circuit.

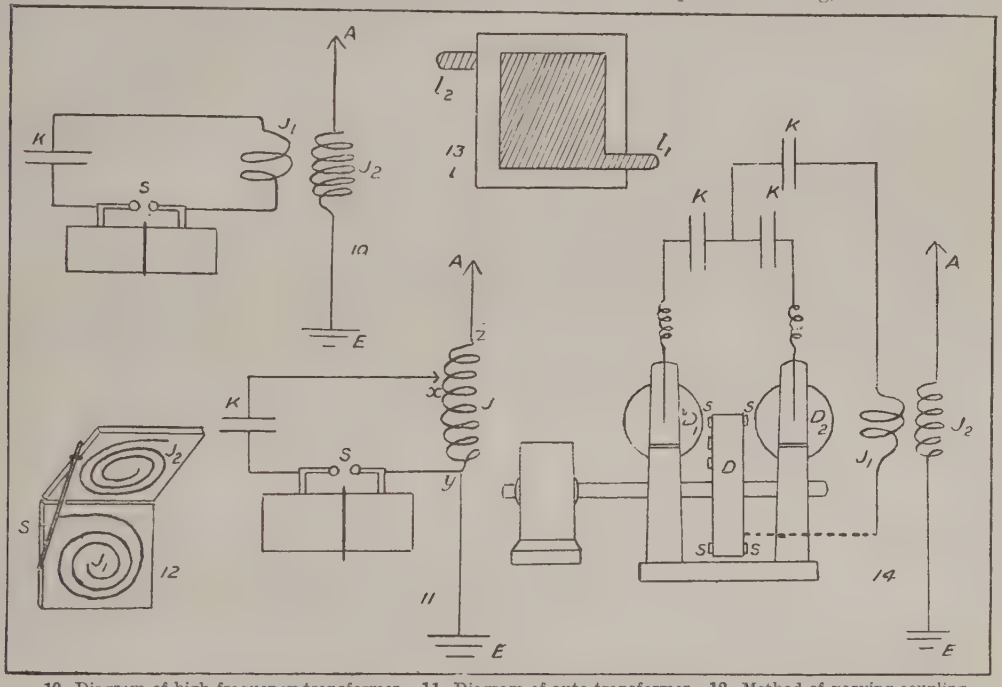
Very smooth and absolutely parallel metal plates are used by Von Lepel, Galletti, Count Arco, and others in the production of quenched sparks. Each plate is separated from the next by mica or paper rings, about one-tenth of a millimetre only in thickness. The plates are kept cool by water or other devices, or by irradiating flanges. By having a number of these plates held together, very numerous spark discharges take place, each spark being instantly quenched, but each giving rise to a quickly damped condenser discharge.

Wave-trains are generated in this way which produce a more or less continuous stream of waves, and a high efficiency results.

Marconi Rotating Spark-gap. It will be interesting at this stage to describe the rotating spark-gap used by Mr. Marconi, by which something of the same kind is produced. One type of discharger is the studded disc pattern. Direct current from a dynamo or battery of storage cells is converted into alternating current by means of a motor-alternator, the latter having attached to its shaft a disc provided near the periphery, with a number of equally spaced studs of metal. The sparks pass during the rotation of the studded disc, D [**14**], between the studs, S S S, and rotating plane discs, D_1, D_2, on either side. Alternating current of about 20,000 volts or more is discharged in this way, and the condensers, KK, and primary inductance, J_1, of the oscillation transformer are connected up in the manner shown in the diagram.

Mr. Marconi made a further advance by employing a smooth disc in place of the studded disc, and or high-tension transformer specially constructed for the purpose. One of the many types of spark discharger is employed, and this is shunted by a battery of Leyden jars acting as the capacity, either the primary coil of a two-coil oscillation transformer or the primary *portion* of a single coil transformer completing the circuit. Flexible wires terminating in clips are used to connect up with the transformer or jigger, so that the primary oscillating circuit can be readily modified to get it into resonance with the secondary; or the wave-length can be altered.

Condensers. The condensers used in wireless telegraphy call for special description. The ordinary Leyden jar consists of a well-insulated glass tube or jar, with an outer and an inner coating of tinfoil. Flat sheets of flint glass are frequently used for larger condensers, with tinfoil sheets placed between; each plate has a lug, as shown in the



10. Diagram of high-frequency transformer 11. Diagram of auto-transformer 12. Method of varying coupling
13. Condenser plates 14. Diagram of Marconi rotating spark-gap

thus succeeded in producing a practically uninterrupted train of waves.

Sending Signals. When using an induction coil or ordinary transformer in the smaller apparatus, signals are given by pressing the Morse key, which makes contact, causes the spark discharge to take place, and thus generates a short wave-train which denotes a signal. In the case of the spark dischargers described above, the current is stopped or interrupted, not switched on, to denote the signals, and in some systems of continuous waves an alternative method is employed, which is described later, of grouping the waves into successive short groups of such frequency that a musical note is created, which is easily detected at the receiving stations.

Ship Transmitters. The transmitter frequently used on ships comprises a specially wound dynamo, which generates alternating current, having a frequency of some 300 complete alternations per second, and this is passed into an induction coil

figure [**13**], and all the lugs of alternate sheets can be connected up. Thus with ten sheets five would be five lugs arranged as l_1, and five arranged as l_2 for the two capacities of the condensers. The tinfoil sheets and glass plates are strongly bound together, and the whole "block" is placed in an ebonite or other box, and the box filled up with oil or vaseline.

Tubular Condenser. A very important form of condenser is that invented by Moscicki. It is a tubular condenser, the inside and outside coatings being of silver, or tin deposited by a special process, with the total exclusion of air bubbles. The glass tubes are made thicker at the ends than in the middles, where the dielectric strain is greatest, and the danger of the glass becoming punctured thereby minimised. The tubes are mounted in "batteries," the frame or stand being heavily insulated with porcelain.

T. THORNE BAKER

The Registers. Volume and Tone. Correct Attack. Faults to be Avoided. Exercises and How to Practise Them.

SINGING PRACTICE

THE human voice is characterised by three distinct qualities of tone, called its registers. The word "register" has been described by Manuel Garcia as "a series of consecutive homogeneous sounds produced by one mechanism, differing essentially from another series of sounds equally homogeneous produced by another mechanism, whatever modifications of *timbre* and of strength they may offer. Each of the three registers has its own extent and sonority, which varies according to the sex of the individual, and the nature of the organ."

There are three registers, called respectively:

1. Open or chest, or *Voce di petto.*
2. Closed or medium, or *Voce di gola.*
3. Head, or *Voce di testa.*

In bygone days, before the study of physiology became general, it was firmly believed and taught that the chest or open notes were actually produced in and emanated from the chest; that the medium were actually produced in and emanated from the throat; and that the head notes were produced in and emanated from the head; and owing to this belief these names, chest, medium and head, first came into use. But the student must banish this absurd idea, all the notes being produced in, and emanating from, the larynx, or voice-box. Although by some authorities these names, chest, medium, and head, are not approved of, to avoid confusion it is advisable that the student should retain them.

The first to be considered is the open, or chest register, which subdivides into the lower and upper chest registers.

The Lower Chest Register. The deepest and strongest tones of the voice belong to the lower chest register. In singing these notes the feeling is as though they were produced in the lowest part of the lungs. If the hand is lightly placed upon the lowest part of the chest, the vibrations can be strongly felt.

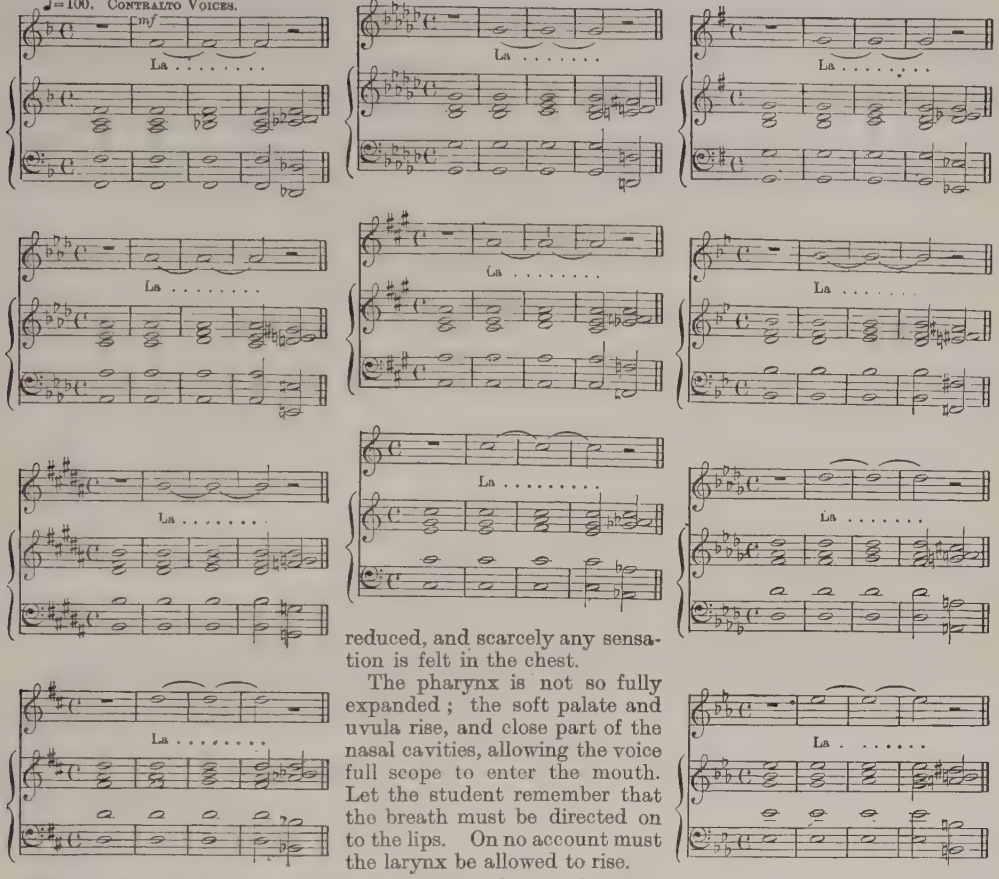
When these notes are correctly sung the whole length, breadth and thickness of the vocal cords vibrate, and the windpipe and pharynx are very much expanded. As the voice ascends the scale, the great tendency of the larynx or voice-box is to rise; this must be carefully guarded against.

The Upper Chest and Medium Registers. All that has been said with regard to the lower chest register equally refers to the upper chest register, except that the vibrations are felt a little higher in the chest, and can be easily detected if the hand is placed upon the upper part. In singing the notes of this register, the whole of the vocal cords do not vibrate. In both registers the utmost care must be used that the notes are not forced. The mouth should feel full of sound. Men (basses and baritones particularly) have better chest notes than women. In female voices, the contralto has the best chest notes; light sopranos have scarcely any.

The medium or closed register like the chest register also includes two series of tone — the lower and upper medium. Some professors call the medium voice the *falsetto*, but since the word "falsetto" refers to notes "above the natural compass of the voice," the word here is a misnomer, for the voice of the medium register is as natural as, if not more so, than that of either of the other registers.

The Lower Medium Register. The sensation felt when these notes are sung is as though the voice emanated from the throat. In singing the notes of this register the vocal cords come closer together; consequently the vibrations are quicker, the volume of tone is

Ex 1. Soprano, Mezzo-soprano, and Contralto Voices.



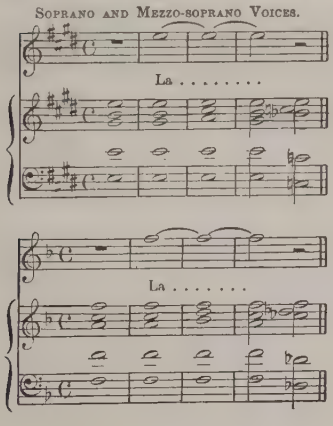
reduced, and scarcely any sensation is felt in the chest.

The pharynx is not so fully expanded; the soft palate and uvula rise, and close part of the nasal cavities, allowing the voice full scope to enter the mouth. Let the student remember that the breath must be directed on to the lips. On no account must the larynx be allowed to rise.

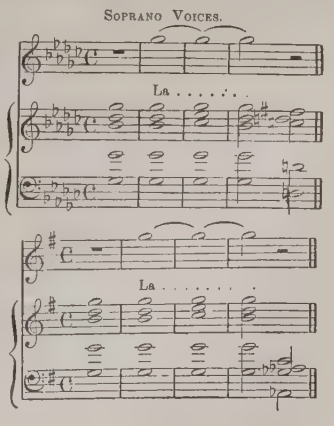
The Upper Medium Register. In producing the notes of the upper medium register the breath must be directed against the middle of the hard palate; the feeling then is as if the voice were produced in the upper part of the mouth, vibrating in the cheek bones. In singing the notes of this register also, the larynx must be kept low.

The Head Register. The sensation experienced when singing the notes of the head register is as though the sound emanated from the back of the head, vibrating in the posterior nasal cavities. The chink of the glottis is very small, the vocal apparatus contracted, and the vocal cords, being at their greatest tension, are very close together. As the student ascends the scale, the aperture or chink of the glottis becomes smaller and smaller until, finally, upon reaching the highest note, the opening is very minute. To produce these notes scarcely any breath is required, and the mouth must be kept wide open.

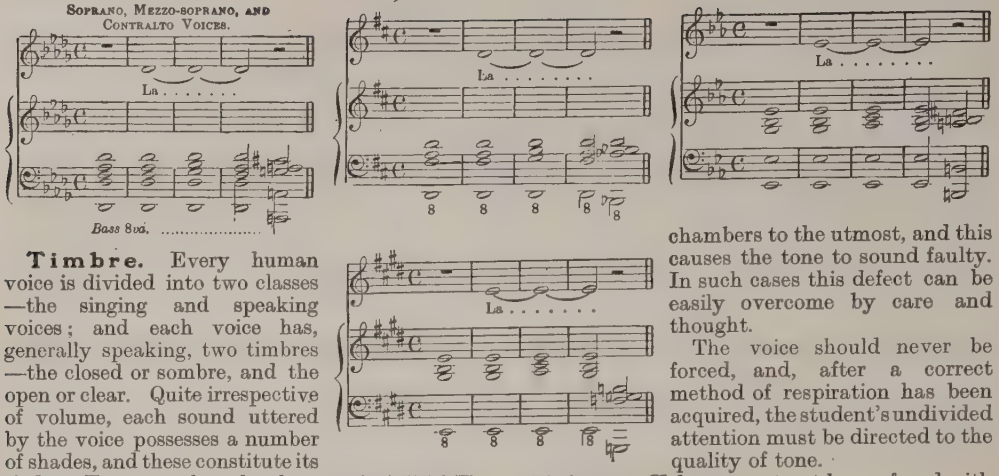
Soprano and Mezzo-soprano Voices.



Soprano Voices.



The soprano, mezzo-soprano, and tenor voices are the most noted for the head register. Occasionally one finds a contralto or baritone who possesses one or two head notes; but, generally speaking, when such is the case it is more than likely that the so-called head notes are nothing but the upper medium notes that have been trained as head notes. In this, as in the other registers, the larynx must be kept low.



Timbre. Every human voice is divided into two classes —the singing and speaking voices; and each voice has, generally speaking, two timbres —the closed or sombre, and the open or clear. Quite irrespective of volume, each sound uttered by the voice possesses a number of shades, and these constitute its *timbre*. For example, take the vowels A E I O U, pronouncing them, Ah, Ay, Ee, O, Oo. Sing or recite each of these vowels on the same note, and with the same intensity of sound, listening carefully. The *tone* of each will be found to be quite different.

Beauty and Quality of Tone. It has been said that no two voices are alike. This being so, each voice must have some special characteristic; but, besides this, it must be either resonant or muffled, mellow or nasal, clear or throaty. The student should bear in mind that the qualities which constitute "beauty of tone" are resonance, purity, and clearness.

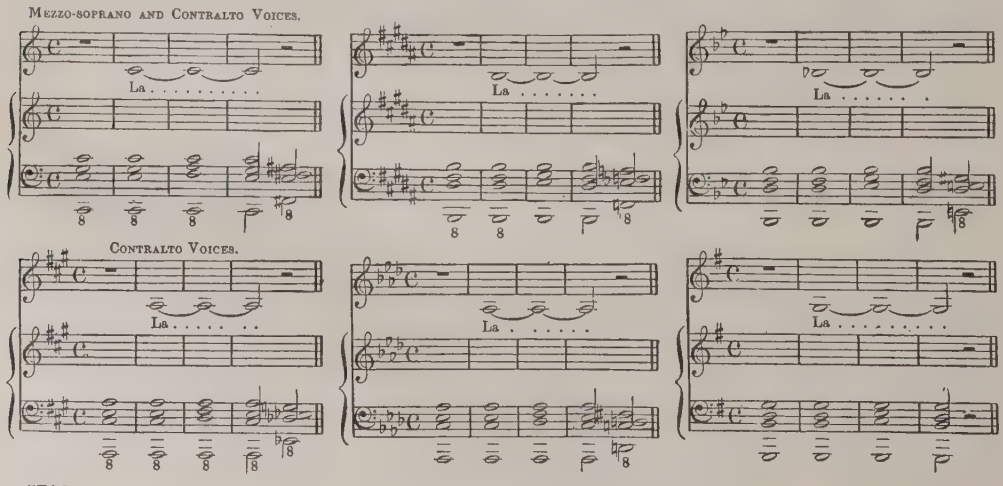
Although all tone is formed in the larynx, its quality depends almost entirely on the resonance chambers. If Nature has endowed the student with open, free, and good resonance chambers—chiefly the pharynx and nasal cavities—together with the free use of the soft palate, uvula, roof of the mouth, tongue, and teeth, it may be affirmed that the quality of the voice will be good—that is, presuming that the vocal cords are not defective. Numbers of people, some through force of habit, some through idleness, never use their resonance chambers to the utmost, and this causes the tone to sound faulty. In such cases this defect can be easily overcome by care and thought.

The voice should never be forced, and, after a correct method of respiration has been acquired, the student's undivided attention must be directed to the quality of tone.

Volume. Volume must not be confused with intensity. Volume is the size or magnitude of the voice, its loudness or softness; and to cultivate it the student must have some knowledge of, if he has not altogether mastered, the art of breathing. To acquire volume, the student must keep his larynx low, all the muscles of the throat free, the breath well under control—too much breath must not be expelled nor any undue pressure put on the vocal cords—the soft palate and uvula must be raised, the chest well expanded, and the tone directed to the front of the mouth, but there must be no forcing.

It should be noted that an intense tone is not necessarily a loud one. It is caused by the pressure of breath on the vocal cords. There are various degrees of intensity. These depend entirely upon the nature of the phrase to be sung or recited; the greater the passion to be portrayed the greater must be the pressure—but not force of breath—upon the vocal cords.

Attack. To attack a note properly is to begin it correctly, not scoop up or slur down to it, but to start it in the very centre. The breath must be well controlled; the attack must be



decided—not necessarily loud—quick and light. Signor Randegger compares it to "touch" in pianoforte playing, and he says "it corresponds to it in quickness, distinctness, lightness, and elasticity."

There is always a tendency in attacking the first note of a song or exercise to let the air rush out, leaving insufficient breath to finish the phrase. It is essential, therefore, that the whole of the vocal apparatus should be *prepared* and in readiness ere the order is mentally given for sound to be produced.

Unfortunately, "poor attack" is a very common fault with students of singing and untrained singers. This is chiefly owing to nervousness, which may cause the singer to attack the tone a little higher or lower than indicated; he will then slur down or scoop up to the correct tone; this is a general fault, but none the less bad. Sometimes a pupil through sheer fright dare not start to sing. Anyone at all afflicted in this way must exert all his will power to overcome his nervousness.

It not infrequently happens that "tightening the throat" to prevent the breath from escaping causes the attack to be incorrect. To repeat what has already been said over and over again, the diaphragm and rib muscles only—*not the throat muscles*—must regulate the breath control. Let the student remember that the attack must be distinct, decided and quick.

Faults to be Guarded Against. Some of the most general faults to be guarded against in singing are these:

1. Bad production—throaty and nasal singing.
2. Breath escape.
3. Tremolo and slurring.
4. Fatigue of the vocal apparatus.
5. Forcing the voice.
6. Tightening the throat muscles.
7. Faulty intonation.
8. High larynx.
9. Wrong position of tongue, soft palate, and uvula.
10. Facial contortions.
11. Movement of the shoulders.
12. Standing on the toes.

Bad production is due to two causes, the first of which is the root of the tongue pressing on the epiglottis, and so preventing a free passage of the breath. It is not an easy fault to overcome, so the student must exercise a good deal of will power and perseverance. Let him open his mouth naturally and fairly wide, and to see what he is doing he must practise before a mirror. Let the tongue be quite limp and lie naturally on the floor of the mouth, keeping the tip against the lower teeth. If he is not already able to keep his tongue "down," he must practise the exercises for the tongue given later.

The second cause of throaty or guttural singing is that the root of the tongue rises and forms a barrier at the back of the mouth. As the natural passage is thus blocked, the breath strikes against the barrier, and some forces its way round the sides of the tongue, some passes into the nasal cavities, and some is driven back into the throat.

When nasal singing is permitted, the tone sounds as though it were actually issuing from the nose. As a matter of fact, in certain cases some of the tone does escape through the nose. It is the result of not raising the soft palate and uvula, and the tongue at such times is often elevated at the root; in this way the breath is prevented from entering the mouth, and an undue amount is forced into the nasal cavities and nostrils. To remedy this, practise the exercises for soft palate and uvula given later on. In some cases nasal singing is due to adenoids. When such is the case, let the student see a doctor and have them removed.

Breath Escape. With beginners, breath escape is a very common fault. It is due almost entirely to a lack of proper breath management, together with a too slack tension of the vocal cords.

What actually takes place is that the breath, for want of control, rushes out through the vocal cords, which are not prepared to receive it. The result is that the greater part of the breath slips through, while only a small portion is used to make the cords vibrate; consequently the listener hears almost more breath than voice.

Let the student sing his exercises *very softly*, feeling all the time that the ribs are well expanded, and that every particle of air coming from the lungs is being used to make the note. This fault, which is really a grave one, since it prevents the voice from carrying, besides impoverishing it, must be corrected as soon as it is detected.

The horrible trembling of the voice, known as the tremolo, gives the listener the impression that the singer is trying to sing two notes and can pitch neither.

It is generally the result of over-straining, or it may be caused by training the chest register too high, forcing the head notes, a wrong method of respiration, ill-health, or nervousness.

If it is caused by over-straining, let the student practise *very softly*, not longer than a quarter of an hour at a time; if by training the chest register too high, be guided by the diagram referring to registers [page 5764], and practise all scales downwards, singing in the medium register as far as able. If by forcing the head notes, let the notes of the head register be sung *very softly* until all signs of the tremolo have disappeared.

If it is caused by a wrong method of respiration, give special attention to carry out all rules laid down for correct breath management; if through ill health, see a doctor at once; and if, lastly, through nervousness, concentrate on a thorough knowledge of exercises and songs. Slurring is dealt with later.

Fatigue of the Vocal Apparatus. Fatigue may be due to various causes, such as forcing, overwork, bad production, wrong method of study, general health, colds, tonsilar enlargement, elongated uvula, adenoids, and so on.

Much has already been said on the dangers of *forcing*. To overwork the voice in the hope of quickly developing it is one of the gravest faults into which a student can fall. A correct time-table for practice is given on page 5772.

The utmost importance is attached to a correct method of study, because when a wrong method is employed, it impedes the progress of voice cultivation very considerably.

The voice is most susceptible to every degree of health; it may be regarded as the barometer of bodily health. It will be observed, therefore, how very important is a high standard of general health. The student must never practise whilst suffering from a cold or sore throat.

Forcing the Voice. Frequently, the beginner in his eagerness to possess a big voice is apt to force it—that is, he is not content to let it develop slowly and naturally but must needs strain or drive it until he has gained size, but, alas! lost the quality. This fault

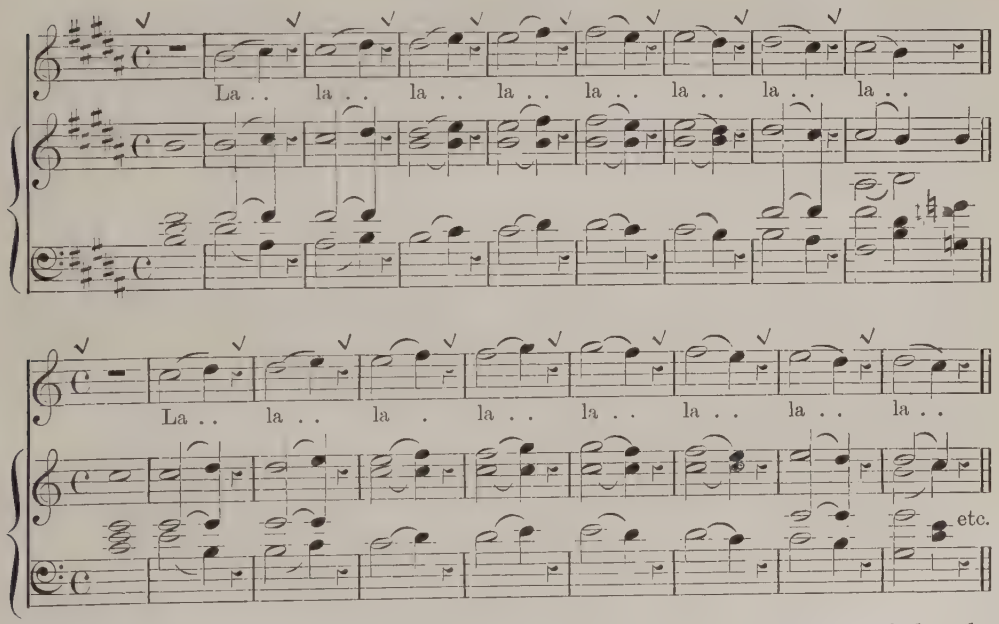
Soprano Voices.



must be rigorously guarded against; if carried too far it spells ruin. Let the student who is thus inclined to force limit himself to singing *softly* until the fault is quite overcome.

The fault of tightening the throat muscles is most prevalent amongst sopranos and tenors. It is generally caused by a faulty method of respiration, and sometimes by singing with the larynx high. Let it be remembered that there must be no feeling of strain or contraction of the throat whatsoever; that a correct method of respiration must be acquired, and that the larynx, or Adam's Apple, be kept low.

Faulty Intonation. A person with faulty intonation is said to sing "out of tune," and to be either "sharp" or "flat." When "sharp" the note he means to sing is a shade higher in pitch than he intends it to be. This is caused either by tightening the throat muscles or by lack of musical ear. If the former is the case, apply the rules given for tightening the throat muscles.

If the " musical ear " is at fault, let the student strike a note on the pianoforte before attempting to sing, listen to it carefully, *mentally* aim at the pitch of the note, sing it, then strike the same note on the pianoforte again, and compare it with the note already sung.

This remedy also applies to lack of musical ear in " flat " singing. Flat singing may be attributed to ill-health, bodily and mental fatigue, lack of musical ear, but most frequently to carelessness.

High Larynx. It is utterly wrong for anyone to sing with a high larynx or voice-box. Because the larynx rises, it may be argued by some people that it is quite correct to sing with it high, but this idea must be abandoned. The larynx rises merely to let food pass more easily down the gullet, not in any way to assist in the production of tone.

Before uttering a sound, let the student open his mouth, lightly place his thumb and first finger on his larynx, or Adam's Apple, then swallow; the Adam's Apple will be found to move upwards and then downwards. When it is down it must be kept so, and in this position let the student sing a note. Let him continue practising this until able to put it into position unconsciously and naturally. When the larynx is *low*, the tone will be open, free and pure.

The Position of the Tongue. At the beginning of this course of study, the student will probably find it difficult to keep his tongue flat, and at the same time loose and free. Notwithstanding, he cannot be too assiduous in his endeavours to control it. If the student opens his mouth and tries to keep his tongue flat, he will find that in nine times out of ten it will immediately rise, either at the tip or the root.

To remedy this, let him take a hand-mirror; open his mouth rather widely, place and keep the tip of the tongue against the inside of the lower teeth, then try and draw the remainder of the tongue backwards, feeling as though the root of the tongue had disappeared. Practise without uttering a sound. Should the tongue still rise, let the student take a paper-knife and lay it along the tongue, trying to realise the sensations felt when the tongue is flat. Slowly, and without moving the tongue in the least degree, withdraw the paper-knife.

When he has repeated this exercise several times, let him again practise without the use of the paper-knife, and persevere until he is able to keep his tongue perfectly flat. On no account must he attempt to sing with the paper-knife in his mouth.

More often through carelessness and ignorance than any other cause are the soft palate and uvula allowed to " hang down " when singing, and thus impede a good production. If they are kept in this position, the tone sounds either nasal or as though it were produced through a thick curtain. The most beneficial exercise for keeping the soft palate and uvula " up " is to stand with the mouth well open, keep the tongue in position, and draw in a slow, deep breath through the mouth, directing the air towards the palate. The student will feel as though he wanted to yawn, and upon looking into his mouth he will observe that his soft palate and uvula have almost disappeared. Let him continue to practise in this way until he is able to raise them without obtaining the effect of yawning.

Mannerisms. Nothing makes a singer appear more ludicrous than facial contortions. Perhaps the most general of these contortions is the raising of one or both of the eyebrows. Other faults are undue raising of the upper lip at either corner, pushing forward the chin, inclining the head to one side, perpetual moistening of the lips, assuming a set smile, constant blinking of the eyelids, quivering of the lower lip, and a nervous twitching of the face generally. All these stupid faults can be overcome if the student will practise carefully before a mirror.

On no account must the shoulders be allowed to rise when singing; should they do so, it may be taken for granted that a wrong method of breathing is employed. As already pointed out, the shoulders should be kept down and well back, in an easy position. This is quite easy if the pupil acquires a proper method of breathing and practises before a mirror.

Another foolish mannerism, which may be easily overcome, is rising on the toes when a high note is sung. This fault is most general with tenors. If the student is inclined to raise himself on his toes, he will be wise to check it at once. Let him observe and carry out the rules for a correct position, then there will be no fear of his falling into this absurd habit.

Order and Length of Practice. The student will do well to follow out the following time-table for daily practice.

1. Long sustained notes on " La " or " Ma," slow exercises, half an hour.
2. Scales, arpeggios, and advanced exercises, half an hour.
3. Solfeggi, half an hour.
4. Songs, half an hour.

On no account must a single practice exceed half an hour.

The above table applies to advanced students only. Elementary students must never practise longer than one quarter of an hour at a single practice. If at first a fifteen minutes' practice is too long, practise ten minutes. The exact order and length of practice for elementary students will be given with each exercise.

The student should never continue practising until he feels fatigued. Sufficient time for rest should be allowed between each practice. An hour or more should elapse after a meal before attempting to sing.

Practising Hints. As regards the duration of each practice, hours of practice, and order of practice, it is of the *utmost importance* that the student should be consistent. He must have method in his work, and never be spasmodic. Unless he practises carefully, thoughtfully, and regularly, he might just as well never practise at all.

The student is well advised never to force his voice, or to shout; not to be too self-satisfied, and think he is perfect when he is only beginning;

never to practise to a pianforte that is out of tune, and never to hurry over the production of his voice.

Let him *study with his brain* more than with his voice; it is useless to practise in "parrot fashion"; he must know and think why he is singing the various exercises; keep his jaw loose and free; avoid all mannerisms; keep to simple and regular diet; and, above all, work hard and diligently, and remember that "of learning there is no end."

Singing Exercises. Alike both in male and female voices, two elements are absolutely necessary for the production of voice—the breath and tension of the vocal cords. The size and depth of the voice greatly depend upon the size and development of the larynx. As already mentioned, men's larynges are much larger than women's; that is why their voices are deeper and less acute.

Now the art of respiration has been studied, and something learnt of the various registers, the student's attention may be directed to the first singing exercises. The female voices will be taken first and then the male ones, but the following remarks apply equally to both of the sexes.

(1) Stand in the position indicated in Respiration [page 5626].

(2) Let the jaw fall naturally.

(3) When the phrase allows, inhale slowly and fully.

(4) The sign ✓ marks the place where the breath has to be inhaled.

It is to be hoped that the student will, if he has not already done so, study the course on THE THEORY OF MUSIC beginning on page 88, so that he may be thoroughly conversant with the terms used in his singing exercises; for example, *mf* (*mezzo forte*) = moderately loud, *f* (*forte*) = loud, and so on. He is urged particularly to study TIME, on page 89. The student should try to realise that the more general musical knowledge he possesses the better will be the results he will obtain.

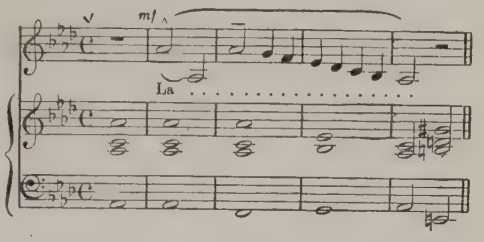
The cultivation of the female voice may begin when the student is in her eighteenth year. The male voice must not be cultivated until the student is nineteen years old.

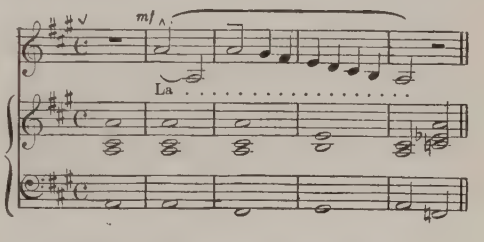
In practising the exercises **1**, **2**, and **3** in this article the mouth must be sufficiently open to admit the *width* of the thumb between the upper and lower teeth. The tongue must lie flat and naturally, with the tip touching the inside gums of the lower front teeth.

The consonants must be very distinctly articulated, and the exercises practised for several weeks—*mezzo forte*, then *forte* and *piano*—usually whilst standing before a mirror.

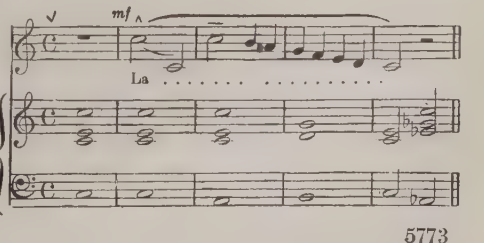
Breath must be inhaled as directed in the first exercise for inhalation, and during inhalation the note about to be sung—especially in Ex. 1—must be sounded on the pianoforte, and listened to carefully. The student must then *mentally* aim at the pitch of the note. This will help to ensure a correct intonation.

Ex. 3. ♩= 100 CONTRALTO VOICES.

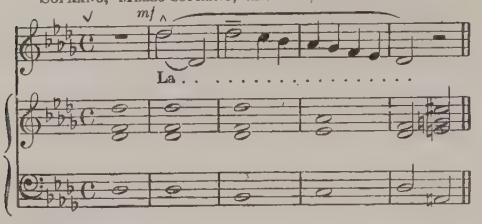


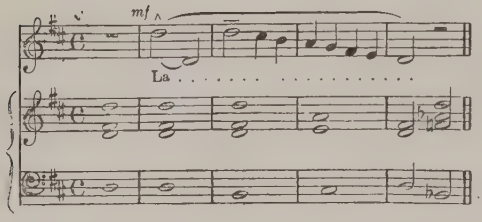


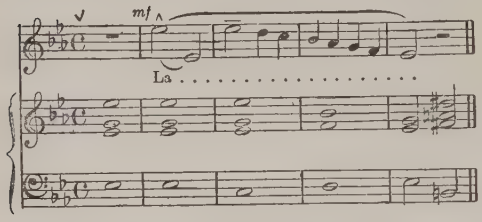
MEZZO-SOPRANO AND CONTRALTO VOICES.



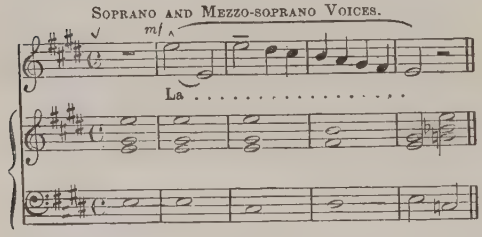
Soprano, Mezzo-soprano, and Contralto Voices.

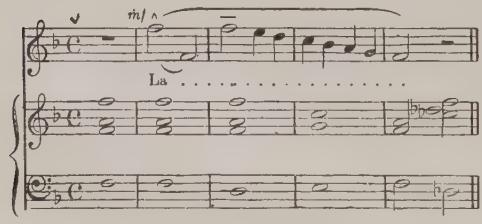




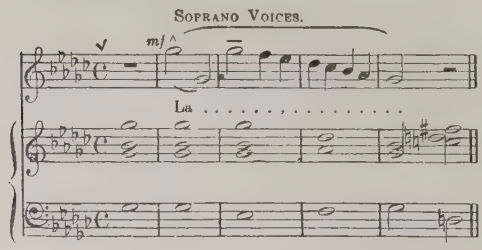


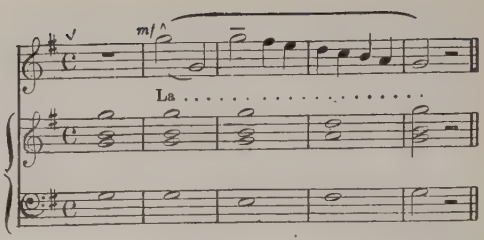
Soprano and Mezzo-soprano Voices.





Soprano Voices.





When singing the notes of

(*a*) the lower medium register— 
inclusive—the breath must be directed on to the lips ;

(*b*) the upper medium register— 
inclusive—to the roof of the mouth ;

(*c*) the head register—  and upwards—to the back of the head ;

(*d*) the upper chest register— 
inclusive—to the front of the mouth ;

(*e*) the lower chest register— 
inclusive—to the front of the mouth.

A Practising Time-table. The following practising table should be adhered to if the best results are to be obtained.

First and second weeks, Exs. **1**, **2**, and **3** in this article.

Third week, Ex. 3, Randegger's "Singing Primer" [page 68]. Exs. **1**, **2**, and **3** in this article also to be practised.

Fourth week, Ex. 4, Randegger's "Singing Primer" [page 79], also exercises of previous weeks.

Fifth week, Ex. 5, Randegger's "Singing Primer" [page 83], also exercises of previous weeks.

Sixth week, Ex 6, Randegger's "Singing Primer" [page 86], also exercises of previous weeks.

Seventh week, Ex. 7, Randegger's "Singing Primer" [page 89], Exs. **1**, **2**, and **3** in this article, and Concone's "Solfeggi," Ex. 1.

All voices must be kept well within their natural compass in practising, and "La"—pronounced as in the word "father"—is the best syllable on which to practise. The first song may be taken about the ninth week.

Concone's solfeggi for the different voices are these: "Soprano, Mezzo-Soprano, and Tenor Voices: Fifty Lessons for the Medium Part of the Voice." "Contralto Voices: Forty Lessons for Contralto." "Baritone and Bass Voices: Forty Lessons for Bass or Baritone." Randegger's editions of the above are recommended, because the phrasing is excellent.

Before beginning to sing a new solfeggio, the student should study it, fully realising with what object the exercise was written, whether for "placing" the voice, the legato or staccato style of singing, sustaining, phrasing, portamento, *mezza voce*, *messi di voce*, blending of the registers, or attack. As before stated, "La" is the most satisfactory syllable to use for solfeggi, and it is

sung to the first note of each phrase, *not repeated with every note.*

A student may find he produces better tones on Ma, Na, Pa, or Da, in which case he must practise on the syllable most suitable.

When he is fairly familiar with the exercises, he must practise them on the different vowel sounds—ah, a, ee, o, oo, prefixing the different consonantal powers.

Basses and contraltos are advised to omit for several weeks the exercises that are to be sung quickly.

The Break. The student may find it difficult to pass smoothly, and without feeling a jerk, from one register to another. This "jerk" is most frequently noticed when passing from a lower to an upper register, especially from the chest to the medium. It is commonly called the "break."

Perhaps of female voices the most troubled in this way are the contraltos. Many untrained ones have a very pronounced "break" somewhere between D (below first line, treble clef) and F (first space, treble clef). No rule can be laid down as to which note the voice must "break" upon—it depends entirely upon the nature of the voice—but on no account must the chest register in any female voice be taken above E (first line, treble clef).

It is often possible to carry the chest register higher than this note, but however easy it may be to the student to do so, it is a very injurious practice. Besides coarsening and hardening the voice, it makes the medium and head registers very weak, and is one of the chief causes of "tremolo." The same applies to the medium register; it must never be carried up beyond F (fifth line, treble clef). Such a practice would make the "head notes" thin and shrill. The most beneficial exercises written for the "blending of registers" may be found in Randegger's "Singing Primer," pages 27–37.

Occasionally it is advisable when singing a descending scale passage to carry the lower medium register beyond its usual limit, and so not use the chest register. When sung in this way the passage is much smoother. On *no account* must the chest register in an ascending scale be taken above its limit. If this is done, the passage is coarse and broken.

As male voices use the chest register almost entirely, they are not affected by this "break."

The above exercises recommended for female voices may be used to advantage by the male voices, tenors beginning on 
, baritones on 
, basses on

Male Voices. Male voices use the lower registers—chest and medium or "voce mista." The production of the "voce mista," or the "mixed voice," which, with tenors, begins at 
, baritones , basses
is very similar to the production of the upper medium register in female voices. When singing these notes "the cavity of the mouth must be completely filled with voice, which, energetically directed towards the arch of the palate, will rebound from it, rendering the sound full and sonorous" (Randegger).

The three exercises already given for female voices are recommended for male voices, and are to be practised in the same order, 1, 2, and 3; but instead of beginning on F (first space, treble clef), the tenor must begin with E flat (first line, treble clef), and practise to G (above treble clef); the baritone with B flat (immediately below middle C), and practise to E flat (fourth space, treble clef); the bass with G (fourth space, bass clef), and practise to C (third space, treble clef). It must be borne in mind that the notes actually sung by the male voices are an *octave lower* than those indicated by the treble clef.

As the voice develops the compass may be extended, either upwards or downwards, or in both directions, as is natural to the voice. The student is advised to limit his compass for several weeks. The directions given for female voices apply equally to male voices.

When singing the notes of the chest registers the throat must be kept well open, the larynx low, and the breath directed *on to the lips.* To produce the "mixed voice" correctly the mouth must be more open than for the chest voice, the tongue lie quite flat, and the breath directed *to the roof of the mouth.*

Signor Randegger says: "Every student of singing should pay particular attention to the various physical sensations experienced in producing the tones of the different registers."

The vibrations of the notes of the different registers are felt:

(*a*) Lower chest, in the lowest part of the chest.

(*b*) Upper chest, in the upper part of the chest.

(*c*) Lower medium, in the lower part of the mouth.

(*d*) Upper medium and "mixed voice," in the front part of the face and towards the forehead.

(*e*) Head, in the back part of the head.

BRITISH FISHERIES

FEW people—even those who are engaged in one or other of its numerous branches—have any adequate idea of the enormous proportions of the British fishing industry. The not infrequent reports of casualties to fishing vessels which are met with in the columns of the daily Press furnish the reader with some idea of the dangers incidental to a calling at all times difficult and hazardous, success in which is only granted to the hardy, the active and bold, and mistakes in which result too often in a speedy death.

Vast Extent of British Fisheries. Before the outbreak of the European war there were over 16,000 sea-going vessels engaged in fishing from the various ports in the British Isles. These vessels are manned by not less than 100,000 fishermen, and in the course of twelve months they land nearly 1,233,000 tons of fish, worth to the fishermen about £14,300,000. By the time this fish has reached the consumer its value will be considerably enhanced, the exact amount paid by the consumer being probably not less than £100,000 per day. The value of the ten most important fishes in the year 1913 is appended:

Herring	£4,572,295
Cod	2,300,119
Haddock	1,891,005
Plaice	1,095,394
Hake	678,981
Soles	474,127
Halibut	460,722
Whiting	390,981
Turbot	302,411
Skates and rays	292,962

For the purpose of fishery statistics a distinction is drawn between *wet* fish and *shell* fish, the former being fishes proper, the latter including oysters, mussels, cockles, crabs, shrimps, and lobsters.

Trawling. Of the various methods of capture in vogue at the present day, undoubtedly the most important is trawling. Trawling is carried on from both steam and sailing vessels, the latter being divided into two classes—the first class consisting of vessels of upwards of 15 tons [1], the second class of vessels below that tonnage. The most remarkable feature in the rise of the trawling industry is the rapid growth both in numbers and in size of the steam trawler, and the consequent supplanting of the smack. In 1913 there were 1359 steam trawlers, 16 motor and 805 sailing trawlers of the first class engaged in fishing from ports in England and Wales.

Steamer versus Smack. The slow method of the cutter is rapidly giving way to the scientific methods of the steam trawler [2]. But since the tendency of modern legislation is to exclude the steam trawler more and more from the inshore waters, there always will be room for the inshore fisherman, who, however, in order to be able to compete in the market with his wealthier and more powerful rival, will have to adopt newer methods. Already on the Continent fishing boats which formerly relied on the wind for their propulsion are being extensively fitted up with motors; and the attention of the English smacksman is earnestly directed to the advisability of inquiring into the advantages of the various internal-combustion engines now on the market.

Trawl Nets. Modern trawl nets are of two main types, the *beam trawl* and the *otter trawl*, the former being almost exclusively used in sailing vessels, the latter in steamers. Both nets are constructed and fished with the same object—they sweep along the ground, and consequently are only adapted for catching those fish which live on or near the bottom. Such fish as soles, dabs, plaice, haddock, and cod are captured by this method of fishing, other methods being employed for herring, mackerel, and similar species which live near the surface. The net attached to the *beam*—which consists of wood, and averages from 20 to 50 ft. in length, according to the size of the vessel using it—is shaped somewhat like a flattened cone [4]. The beam is affixed at each end to a triangular iron frame—the *trawl head*—these frames being dragged along the bottom with the beam attached to the apex of the triangle so that when in action the beam is raised a few feet above the ground and forms the upper boundary of the mouth of the trawl [3]. The lower margin of the trawl mouth consists of a heavy rope, the *foot-rope*, considerably longer than the beam, so that it curves backwards behind the beam, and, unlike it, is in contact with the ground. The terminal portion of the net is known as the *cod-end*, and is fastened by a rope which can be detached when the trawl is hoisted on deck, the catch being thus easily liberated. At intervals in the net there are net-like contrivances known as *pockets*, which, in effect, minimise the efforts of fish to escape through the mouth of the net. The trawl is towed along by two ropes, the *bridles*, which are attached to the trawl-heads, and united at the *shackle* to form a single towing rope —the *trawl-warp*.

Improvement of the Trawl. About the year 1893 a modification of the trawl was introduced [5], and this may briefly be described as a supersession of the *beam* by means of a rope called the *head-line*, the main advantages being a greater length of opening, head-lines of over a hundred feet in length being common. At either end of the *foot-rope* is attached a heavy wooden door-like board, the *otter-board*, and to these boards the *trawl-ropes* are attached in such a manner that the former are dragged along the bottom on one of their long edges, the surface of the board being inclined at an angle to the direction in which the net is being dragged, so that the mouth of the net is kept open. There are two warps used with the otter-trawl, instead of one only as in the beam-trawl. When the trawl is shot and on the bottom, the steamer tows it along slowly, a fair average speed being about three miles an hour. The pressure of water is exercised in such a manner that the boards are forced upwards and apart, the mouth of the net being thus kept in a distended position. The *head-line*, which is a few feet from the bottom, passes over the fish before they are disturbed by

the *foot-rope*, which curves backwards as described above. The fish when disturbed swim upwards and strike the netting of the upper part of the net, which is now well above them, and the pressure of the water forces them into the net towards the *cod-end*. The lower part of the net, which runs along the bottom, is subject to considerable wear and tear, and is strengthened by apron-like pieces of netting, which save the net proper.

The Seine. Intermediate between the *trawl* and the *drift-net* described below is the *seine*, which resembles the trawl in its being dragged through the water, and the drift-net in that it is a vertical wall of netting. It is almost exclusively employed in inshore fishing, and for such fish as herring, mackerel, pilchards, bass, and mullet. The seine consists of a vertical wall of netting, to the upper part of which corks or *floats* are attached; to the lower part, weights or *sinkers*. It is used from two boats, or from the shore with one boat. In either case the net is piled up in the stern of the boat which moves. In this way an area is surrounded by the net, which is pulled in gradually towards the shore.

1. FIRST-CLASS DEEP-SEA SAILING TRAWLER
(The beam trawl is on deck)

Drift Netting. While *trawling* and *lining* are the methods employed for the capture of bottom-living fish, for those fish which live in intermediate depths to the surface other methods have to be used. Such a method is the *drift-net*, extensively practised in the capture of herring, mackerel, and pilchards. A drift-net carried by a Scottish sailing boat ("Fifie") of the largest class usually amounts to 42,000 square yards, and consists of 70 nets, each of an area of 600 square yards. This *fleet* of nets extends to 2590 yards. The whole net hangs vertically in the water, forming a wall of network against which the fish impinge. The upper surface of the net is attached to a rope supported by cork floats, the whole apparatus being so arranged that it can be fished at any required depth, and when fishing it drifts with the tide. Nets of different-sized mesh are used according to the fish which it is desired to capture, the usual size for mackerel being 1¼ in. from knot to knot, for herring 1 in., and for pilchards ¾ in. When a fish strikes against the net its head passes through, but owing to the increasing size of its body the fish is fixed in the mesh. Even in this method of fishing we find steamers extensively employed. In 1913 there were 864 steam drifters engaged in Scotland, where the sail drifter is rapidly disappearing.

2. FLEETWOOD STEAM TRAWLER

Drift nets were originally made of hemp in Ireland, and in the Isle of Man of flax, but at the present day they are chiefly made of cotton, the greater lightness of which has enabled fishermen to extend the length of their nets. The introduction of an auxiliary engine for hauling has also enabled fishermen to extend the length of the nets.

The Trammel Net. Except for the fact that it is fixed, the *trammel* might well be regarded as an offshoot of the drift-net. It consists of three vertical nets fastened together at the top, bottom, and ends. The middle net *hangs loose*, and is of small mesh. The outer nets, one on either surface, have wide meshes, from three to six inches or more from knot to knot, and are of coarser thread than the inner net. The fish swims along until it strikes the outer net; then it darts forward suddenly, pushes against the central net, and carries a portion of it through the large meshed net on the other side. The fish is then safely trapped in a sort of pocket, or, technically, is *trammelled*.

The Stake Net. The *stake net* is a vertical wall of netting supported by stakes, and is a fixed apparatus employed in estuaries. It is a very ancient method of fishing, and a very destructive one; consequently its use is restricted as far as possible. As a general rule, these nets may not now be set right across a stream or channel, and there are other regulations, which vary in different localities, as to the size of mesh and the total length of the net. The varieties of stake net are legion, but it is in the United States that they have reached their maximum development. In this country the nets are usually a simple wall with or without a trap-like arrangement at the fishing end. They are set at right angles to the direction of the tide, and may be calculated at certain seasons of the year to yield the maximum of result with the minimum of effort.

Line Fishing. A large quantity of deep-sea fish is still caught by *lining*, and this is more particularly the case in Scotland, where, in 1913, twenty steamers were exclusively engaged in this method of fishing. Twenty per cent. of the total quantity of demersal fish landed in Scotland is caught by liners. A line as used on a steam vessel is usually several miles in length, and at intervals of about 6 ft. is provided with pieces of line, the *snoods*, to which baited hooks are attached. The position of the line is marked by buoys. The hooks are usually baited with mussels, whelks, or herring, and the lines are shot in the evening, and fished in the morning. The line can be used on rocky ground where trawling is obviously impossible.

Fishing for Crustacea. In addition to the various methods of fishing for *wet* fish, which have been described, there is an extensive fishery for various crustacea, such as shrimps, prawns, lobsters, and crabs, the value of which to the fishermen of the British Isles is certainly not less
